**Corneal Lacerations.** Signs of corneal perforation (full-thickness corneal lacerations) include loss of anterior chamber depth, teardrop-shaped pupil caused by iris prolapse through the corneal laceration, and blood in the anterior chamber (Fig. 69-14). Small corneal lacerations can be difficult to diagnose. If aqueous humor is leaking from the corneal wound, it appears as streaming fluorescent dye surrounded by an orange pool of solution on slit-lamp examination (Seidel’s test). Full-thickness corneal lacerations are managed as described for blunt traumatic globe rupture.

Superficial partial-thickness corneal lacerations without a widened wound can be treated with a cycloplegic, topical antibiotic, and a pressure patch. Repairs of partial-thickness corneal lacerations requiring suture closure are performed in the operating room.

**Scleral Lacerations.** Penetrating scleral lacerations occur with the signs and symptoms of blunt globe rupture. Globe perforation may be unrecognized in the absence of significant physical examination findings.

**Orbital and Intraocular Foreign Bodies**

**Clinical Features and Management.** Any orbital and intraocular penetration should be approached with the possibility of intracranial injury.

Small intraocular and intraorbital foreign bodies can occur with any perforating injury and be difficult to diagnose. Physical examination of the eye may be completely normal at initial presentation. Occult foreign bodies should be suspected with
any penetrating injury associated with mechanical grinding, sanding, drilling, and hammering. Plain orbital films, orbital CT scan, magnetic resonance imaging (MRI) scans, and ultrasonography aid in diagnosis. Although the decision to use one modality over another is dictated by individual clinical circumstances, an orbital CT scan is probably the most useful diagnostic tool. The MRI scan should not be used when an iron-containing foreign body is suspected.

Treatment of intraocular foreign bodies is dictated by clinical circumstances and is left to the ophthalmologist. Patients with acute intraocular foreign bodies should be hospitalized, have nothing by mouth, have a protective shield placed, and be given antibiotics. Generally speaking, acute intraocular foreign bodies are surgically removed. Plastic, glass, and many metals are relatively inert, and their nonacute removal is sometimes likely to cause more damage than their permanent presence. Organic foreign bodies are more important to remove because of their propensity for infection. Siderous oxidation of ocular tissues is a late complication of iron-containing intraocular foreign bodies that can lead to visual loss. Chalcosis, a sterile inflammatory reaction to copper-containing compounds, may occur, requiring removal of the offending object.

Complications of Ocular Trauma

Clinical Features and Management

Post-traumatic Corneal Ulcers. Any defect in the corneal epithelium may become infected with bacteria or fungi. Ulcerations are surrounded by a cloudy white or gray-appearing cornea (Fig. 69-15). A reactive sterile hypopyon (pus or pus-like fluid) may be present in the anterior chamber. Emergent ophthalmologic consultation is needed. Treatment includes cycloplegia, topical antibiotics, and often admission to the hospital. Corneal perforation is a complication.

Endophthalmitis. Endophthalmitis is an infection involving the deep structures of the eye, namely the anterior, posterior, and vitreous chambers. Patients complain of pain and visual loss. Examination reveals decreased visual acuity, chemosis, and hyperemia of the conjunctiva, and the infected chambers are hazy or opaque (Fig. 69-16). Endophthalmitis is a complication of blunt globe rupture, penetrating eye injury, foreign bodies, and ocular surgery. Prompt diagnosis and early treatment with intraocular and systemic antibiotics are important in the successful management of post-traumatic endophthalmitis. Common pathogens are *Staphylococcus*, *Streptococcus*, and *Bacillus*. Topical, intravitreal, and systemic antibiotics are all used.

Sympathetic Ophthalmia. This is an inflammation that occurs in the uninjured eye weeks to months after the initial insult to the injured eye. It is thought to be an autoimmune response to the normally sequestered uveal tissues of the injured eye becoming exposed with injury. Patients have pain, photophobia, and decreased visual acuity. Treatment includes steroids and other immunosuppressive agents. Enucleation of the blind injured eye can reduce symptoms even after the sympathetic ophthalmia has developed.

DISEASE OF THE CONJUNCTIVA

Clinical Features and Management

Conjunctivitis

 Conjunctivitis is an inflammation of the bulbar and palpebral conjunctiva caused by various viral, bacterial, mechanical, allergic, and toxic agents. When the cornea is also involved, it is known as keratoconjunctivitis. Multiple viral and bacterial pathogens are responsible for acute conjunctivitis. Adenovirus, coxsackievirus, and enteroviruses have been isolated as causes of conjunctivitis. Common bacterial agents include *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Staphylococcus* organisms, *Moraxella catarrhalis*, and *Neisseria gonorrhoeae*. Less common bacterial causes are *Klebsiella* and *Pseudomonas*.

Acute Bacterial Conjunctivitis. Patients complain of pinkeye, redness, a foreign body sensation, lid swelling, drainage, and eye crusting in the morning. Photophobia and visual loss are notably absent.

Treatment of acute bacterial conjunctivitis includes warm compresses and topical ophthalmic antibiotics. In uncomplicated acute bacterial conjunctivitis, topical trimethoprim and polymyxin are a good initial selection. Other agents commonly used include sodium sulfacetamide, ciprofloxacin, ofloxacin, gatifloxacin, and erythromycin. Neomycin ophthalmic solutions should be avoided because of the high incidence of hypersensitivity reactions. Ophthalmic ointments provide a soothing effect and have prolonged contact with the ocular surface while ophthalmic drops do not interfere with vision. Medications should be continued for 7 days. Corticosteroids and eye patching should be avoided.

Cultures are indicated when symptoms are severe or when prior treatment has been inadequate or unsuccessful. Complications of acute bacterial conjunctivitis include corneal ulcer formation, keratitis, and corneal perforation. Patients...
with complicated bacterial conjunctivitis should be referred to an ophthalmologist.

Acute bacterial infection caused by *N. gonorrhoeae* is uncommon but important because of its significant complications. Infection results from direct contact with individuals infected with urethritis or pelvic inflammatory disease. Signs and symptoms are markedly increased, including a copious purulent discharge. Gram’s stain may reveal the diagnosis, although cultures are more sensitive.

Treatment is more aggressive than with other causes of bacterial conjunctivitis. Hospital admission for IV antibiotics, saline irrigation, and topical ophthalmic antibiotics is warranted in moderate and severe cases and any patient with corneal involvement. Outpatient management may be used in selected mild cases with ceftriaxone 1 g intramuscularly as a single dose, topical erythromycin ointment, and saline solution irrigation of the conjunctiva. A substantial proportion of patients have concomitant *Chlamydia trachomatis* infection and should be treated with oral doxycycline, tetracycline, or erythromycin (20 mg/kg) or a single dose of 1 g of azithromycin.

**Viral Conjunctivitis.** Viral infection is the most common cause of conjunctivitis. Several types of viruses can cause conjunctival infection; however, adenovirus is the most common viral cause. Viral conjunctivitis generally produces more redness, itching, eye irritation, a clear watery discharge (which can become purulent appearing), preauricular lymphadenopathy, and lasts longer than does bacterial conjunctivitis (Fig. 69-17). It commonly occurs in the setting of other viral symptoms (e.g., fever, myalgias, malaise). The patient usually complains of initial eye irritation in one eye that spreads to the other eye a few days later.

Viral conjunctivitis is very contagious for 10 to 12 days after onset, and appropriate preventive measure, such as frequent handwashing, should be taken. Treatment consists of artificial tears and cool compresses. A vasoconstrictor and antihistamine combination can be used if itching is severe. Sometimes it may be difficult to differentiate between viral and bacterial conjunctivitis. The emergency physician can use some clues in the history and physical examination to point to one direction. Not all patients with an erythematous eye need antibiotics. The emergency physician should use his or her clinical judgment to decide which patients may need antibiotics. Topical antibiotics should be given only to patients in whom bacterial superinfection is suspected. Since viral conjunctivitis is a self-limited and benign condition, the majority of patients require only supportive care with artificial tears, cold compresses, and decongestants.

**Ophthalmia Neonatorum.** Conjunctivitis that occurs within the first month of life is termed ophthalmia neonatorum and has several causes. A bacterial cause should be investigated with Gram’s stain and cultures within the first 2 weeks of life. *N. gonorrhoeae* and *Chlamydia* are both transmitted from mother to infant through the birth canal.

Infected with *N. gonorrhoeae* is manifest within 2 to 4 days after birth. The infant should be carefully examined for evidence of systemic gonococcal infection. Hospitalization and blood and cerebrospinal fluid examination may be indicated. Nonsystemically infected neonates can be effectively treated with a single dose of ceftriaxone, 125 mg intramuscularly, topical polymyxin B-bacitracin ointment, and saline washes. These patients should also be treated for ocular chlamydial infection. Close follow-up is needed.

Infants with chlamydial infection develop symptoms between 5 and 13 days after birth. Topical erythromycin ointment and oral erythromycin are the antibiotics used. Treatment is for 14 days.

Chemical conjunctivitis from antibiotic ointment administration immediately after delivery occurs within 1 to 2 days of birth but should not be the diagnosis if the infant has significant symptoms, the time course is inappropriate, or other historical and physical examination parameters are not classic. In such cases, a bacterial cause should be assumed.

In neonates with no information from stains or cultures and in whom an organism is not known or suspected, topical erythromycin ointment and oral erythromycin are utilized.

**Miscellaneous Conjunctivitis.** Allergic conjunctivitis is common. Allergens include drugs, cosmetics, and environmental agents. Eye itching is generally more pronounced in patients with allergic conjunctivitis and tends to be bilateral. Artificial tears, cool compresses, combination topical ocular decongestants, topical vasoconstrictor-antihistamine combinations, and topical nonsteroidal agents may be used for treatment. Other types of conjunctivitis include toxic conjunctivitis from topical ocular medications (aminoglycosides, antivirals, and preservatives), molluscum contagiosum, and chronic conjunctivitis.

### DISEASE OF THE CORNEA

**Differential Considerations**

**Clinical Features and Management**

**Pterygium and Pinguecula.** A pterygium is a wedge-shaped area of conjunctival fibrovascular tissue that extends onto the cornea. Pterygium is associated with increased exposure to ultraviolet light exposure, especially in subtropical and tropical climates. Patients usually present with eye irritation as well as visual changes if a significant portion of the cornea is involved. A pinguecula is white or yellow, flat to slightly raised tissue on the conjunctiva, immediately next to but not on the cornea. Pinguecula can also be associated with ultraviolet light exposure or dryness. Patients can be asymptomatic or present with irritation and redness. Treatment of pterygium and pinguecula includes protection from wind, dust, sunlight, and artificial tears. An inflamed pinguecula can be treated with a short course of a topical nonsteroidal agent. Nonemergent referral to an ophthalmologist is recommended. Surgical removal is possible for selected individuals.

**Superficial Punctate Keratitis.** Superficial punctate keratitis consists of superficial, multiple, pinpoint corneal epithelial defects. Patients present with pain, photophobia, redness, and a foreign
body sensation. Superficial punctate keratitis is a nonspecific finding that is seen in many conditions. The most common precipitating conditions are ultraviolet burns (welders or sun lamps), conjunctivitis, topical eye drug toxicity (neomycin, gentamicin, and drugs with preservatives, including artificial tears), contact lens disorders, dry eye and exposure keratopathy, blepharitis, mild chemical injury, and minor trauma. Specific treatment is aimed at the underlying offending cause. Nonspecific treatment for a significant non–contact lens–associated superficial punctate keratitis includes nonpreserved artificial tears, topical antibiotics such as trimethoprim-polymyxin drops, and cycloplegia. Patients with a significant contact lens–associated superficial punctate keratitis should stop wearing their contact lenses and be treated with a topical fluoroquinolone or tobramycin drops during the day and ointment at night. Patients should have ophthalmologic follow-up the next day.

**Corneal Ulcers and Infiltrate from Infection.** Corneal infiltrates arise as a focal white opacity without an epithelial defect. Corneal ulcers have an overlying corneal epithelial defect that stains with fluorescein in addition to the corneal infiltrate. Patients present with pain, redness, photophobia, and decreased vision. The most common cause is bacterial, but fungal and herpes simplex infections are also possible. Patients should be immediately referred to an ophthalmologist for corneal culturing before treatment is initiated.

**Herpes Simplex Infections.** Infection with herpes simplex may be either primary or reactivation of preexisting disease. Symptoms include foreign body sensation, tearing, photophobia, clear discharge, and decreased visual acuity. Physical examination reveals a red eye and may or may not include the classic herpetic vesicles located on the lids or conjunctiva. Corneal involvement is seen on slit-lamp examination and may appear as a superficial punctate keratitis, ulcer, or the classical dendritic lesions (Fig. 69-18). Treatment for epithelial keratitis consists of topical antiviral agents such as trifluridine 1% every 2 hours for 14 to 21 days. Topical prophylactic antibiotics and cycloplegia are also employed. Topical steroids are contraindicated in corneal epithelial disease but have proved to be beneficial in stromal disease. Emerging ophthalmologic consultation is advised.

**Herpes Zoster Infection.** Herpes zoster keratoconjunctivitis occurs as a result of activation of the virus along the ophthalmic division of the trigeminal nerve. The rash follows dermatomal patterns, involves the forehead and upper eyelid, and produces significant pain. Involvement of the nasociliary branch of the trigeminal nerve, manifested by zoster lesions on the tip of the nose (Hutchinson’s sign), is associated with a 76% risk of ocular involvement versus 34% risk if the nerve is not involved. Ophthalmic herpes zoster accounts for approximately 10 to 20% of all zoster cases and mandates emergent ophthalmologic consultation. Treatment is complex and depends on the type, location, and degree of ocular involvement. Antiviral agents (acyclovir, valacyclovir, or famciclovir), topical steroid agents, as well as topical antibiotics are used. Early treatment with antiviral therapy within 72 hours of the onset of the rash has been shown to reduce acute pain and ocular complications. Some patients may require admission for IV antiviral therapy while many can be treated as outpatients with close ophthalmologic follow-up. In a recent study, orally administered valacyclovir resulted in substantial virostatic lesions (Fig. 69-18). Treatment for epithelial keratitis includes nonpreserved topical prophylactic antibiotics and ointment. Topical fluoroquinolone or tobramycin drops during the day and ointment at night. Patients should have ophthalmologic follow-up the next day.

**Contact Lens Complications.** The common complications of contact lens use involving the cornea include mechanical damage such as abrasions, corneal neovascularization, infections producing corneal ulcers, hypersensitivity or toxicity reactions to preservatives in solutions, and contact lens deposits. *Pseudomonas* is an important pathogen in contact lens–acquired infections. If infection or abrasion is suspected, a topical fluoroquinolone is used six to eight times daily in the affected eye to cover for *Pseudomonas*. If no significant signs or symptoms exist that indicate corneal infection, the patient should discontinue contact lens use and follow up with his or her ophthalmologist. When corneal infection is present or suspected, immediate ophthalmologic consultation is indicated.

**DISORDERS OF THE LIDS AND OCULAR SOFT TISSUES**

**Differential Considerations**

**Clinical Features and Management**

**Hordeolum and Chalazion.** Hordeolums and chalazions are localized, nodular, inflammatory processes of the eyelids. Hordeolums, also known as styes, are acute inflammations of the glands of Zeis or hair follicles caused most commonly by *Staphylococcus* species. A chalazion is the result of an obstructed meibomian gland that results in swelling within the lid surface with the lid margin being normal. Symptoms and signs include pain, swelling, and redness (Fig. 69-19). Spontaneous rupture may occur, and most resolve with warm compresses applied for 15
Lulitis can result in meningitis and cavernous sinus thrombosis (CT scan of brain and orbits) and hospitalization. Orbital cellulitis is characterized by a continuum of disease, and treatment is tailored to the degree of the patient’s toxicity. Systemically ill patients should be hospitalized.

**Dacryocystitis.** Dacryocystitis is an acute infection of the lacrimal sac from nasolacrimal duct obstruction. The most common organism is *Staphylococcus aureus*. Symptoms and signs include pain, tenderness, swelling, and erythema over the lacrimal sac (Fig. 69-20). Pressure over the sac may express purulent material from the puncta. Treatment includes topical ocular and oral anti-staphylococcal antibiotics and warm compresses. Gentle massage of the area during warm compress application may help decompress purulent material and relieve symptoms.

**Blepharitis.** Patients present with thickened, mattered, red eyelid margins with pronounced blood vessels. Patients complain of burning, itching, tearing, foreign body sensation, and morning crusting of the eyelids. Treatment includes rubbing the eyelid margins with a mild shampoo using a cotton-tipped applicator or cloth twice per day, warm compresses, and artificial tears. Severe blepharitis can also be treated with topical antibiotic ointment applied at night.

**Preseptal Cellulitis.** Patients present with lid erythema and warmth, tenderness, and swelling and may have a low-grade fever. Preseptal cellulitis is more common in younger children, with sinusitis being the most common cause. It may also occur after minor skin trauma such as an insect bite or spread from a focus of impetigo. It is important to note the absence of findings associated with orbital (postseptal) cellulitis (i.e., proptosis, restriction of extraocular movements, pain with eye movement, and patient’s toxicity). If any of these findings are present, orbital cellulitis or abscess should be suspected and the patient managed more aggressively with imaging studies (CT scan of brain and orbits) and hospitalization. Orbital cellulitis can result in meningitis and cavernous sinus thrombosis if it is not recognized or left untreated. Preseptal cellulitis is characterized by a continuum of disease, and treatment is tailored to the degree of the patient’s toxicity. Mild disease can be treated on an outpatient basis with oral antibiotics, but hospitalization with IV antibiotics may be needed for moderate to severe disease and for younger children. The choice of antibiotic should include coverage for *Streptococcus and Staphylococcus* species, since these are the most common pathogens.

Adults should be treated with amoxicillin/clavulanate 500 mg PO three times daily for 10 to 14 days as outpatients or an IV second- or third-generation cephalosporin for inpatient treatment. Due to the increased incidence of community-acquired methicillin-resistant *S. aureus*, empirical coverage with vancomycin or clindamycin should also be considered. If the patient is admitted and shows improvement with IV antibiotics within 48 to 72 hours, a trial of oral antibiotics as outpatient therapy can be considered with close follow-up.

## GLAUCOMA

**Clinical Features and Management**

Aqueous humor is produced by the ciliary processes. In addition to providing structural support to the eye, aqueous humor delivers oxygen and nutrients to the avascular lens and cornea and removes their waste products. This fluid passes from the posterior chamber to the anterior chamber through the pupillary aperture. The aqueous humor is transported into the trabecular meshwork located at the anterior chamber angle formed by the junction of the root of the iris and the peripheral cornea. The trabecular meshwork serves as a one-way valve and filter for the aqueous humor into the canal of Schlemm, which in turn drains into episcleral veins.

Intraocular pressure is determined by the rate of aqueous humor production relative to its outflow and removal. Normal intraocular pressure is between 10 and 20 mm Hg.

Glaucoma is an optic neuropathy caused by increased intraocular pressure. Irreparable optic nerve damage can result. The simplest classification is to divide the glaucomas into primary or secondary and open angle or closed angle. Secondary glaucoma is associated with another ocular or nonocular event, whereas primary glaucoma is not. Closed-angle glaucoma is caused when the anterior chamber angle is narrowed, reducing the outflow and removal of aqueous humor, whereas open-angle glaucoma occurs with a normal anterior chamber angle.

Patients vary in their susceptibility to a given level of intraocular pressure. Some may develop significant optic nerve findings despite a relatively low intraocular pressure (low-tension glaucoma), whereas others may have scant optic nerve changes despite relatively high intraocular pressure (ocular hypertension).

**Primary Open-Angle Glaucoma**

Primary open-angle glaucoma is the most common form of glaucoma and is a leading cause of blindness in the United States. There is increased resistance to aqueous humor outflow through the trabecular meshwork. Primary open-angle glaucoma is generally insidious, slowly progressive, chronic, bilateral, and painless. Advanced disease occurs before symptoms. Symptoms begin as visual field loss at the periphery that progresses centrally. Signs include an optic cup to optic nerve ratio of greater than 0.6. Other findings include vertically oval, deep, and pale optic cups, with nasal displacement of blood vessels.

The three treatment options are medications, argon laser trabeculoplasty, and guarded filtration surgery. Initial treatment is generally with one or more topical agents. Beta-blockers, selective α₁-receptor agonists, carbonic anhydrase inhibitors, prostaglandin agonists, miotics, and sympathomimetics are all used.

Topical ocular medications are absorbed and may produce significant systemic side effects. Topical beta-blockers have produced asthma, heart block, congestive heart failure, hypoglycemia, and depression. Adrenergics have produced hypertension and cardiac dysrhythmias, whereas carbonic anhydrase inhibitors have produced systemic side effects. Other systemic side effects include dizziness, headache, dry mouth, and allergic reactions.
inhibitors have produced renal calculi and hypokalemia. Complications may arise as a result of drug interaction. Prolonged apnea, for example, has resulted when succinylcholine has been given to a patient receiving topical ophthalmologic acetylcholinesterase inhibitors.

Secondary Open-Angle Glaucoma

Secondary open-angle glaucoma can have a number of causes, including lens induced, inflammatory, exfoliative, pigmented, steroid induced, traumatic, angle recession, and ocular tumor.

Treatment is directed to the offending mechanism and includes the methods used for primary open-angle glaucoma.

Primary Angle Closure Glaucoma

Primary angle closure glaucoma occurs in patients who have anatomically small and shallow anterior chambers. This anatomic variation results in the iris being nearly in contact with the lens, resulting in resistance to aqueous humor flow from the posterior to anterior chamber. This is called pupillary block.

Attacks of primary angle closure glaucoma are precipitated by pupillary dilatation. Dimly lit rooms, emotional upset, and various anticholinergic and sympathomimetic medications are common precipitating events. The dilatation of the pupil increases the degree of pupillary block, leading to an accumulation of aqueous humor in the posterior chamber. The iris bulges forward, obliterating the angle between the cornea and iris, obstructing the trabecular meshwork, decreasing outflow, and leading to a rapid rise in intraocular pressure.

A second, less common mechanism of acute angle closure glaucoma, produced without pupillary block, is caused by a flat or plateau iris. This leads to a narrow angle recess. Dilatation of the pupil causes the iris to fold and bunch over the angle, blocking aqueous humor outflow into the trabecular meshwork.

Symptoms are abrupt in onset and include severe eye pain, blurred vision, headache, nausea, vomiting, and occasionally abdominal pain. Patients see a halo around lights. Signs include conjunctival injection and a cloudy (steamy) cornea with a midpositioned to dilated pupil that is sluggish or fixed (Fig. 69-21). Visual acuity may be significantly decreased, and intraocular pressures are markedly elevated.

Treatment should begin promptly. If visual acuity is markedly reduced (hand movements or less), a combination of conjunctival injection and a cloudy (steamy) cornea with a blurred vision, headache, nausea, vomiting, and occasionally meshwork. Blocking aqueous humor outflow into the trabecular meshwork of the pupil causes the iris to fold and bunch over the angle, or plateau iris. This leads to a narrow angle recess. Dilatation of the pupil causes the iris to fold and bunch over the angle, leading to a rapid rise in intraocular pressure.

In the setting of a severe attack, acetazolamide, a carbonic anhydrase inhibitor, is given in an IV dose of 250 to 500 mg, and mannitol 1 to 2 g/kg over 45 minutes. Sedatives and antiemetics may be administered as needed. Emergent ophthalmologic consultation is warranted.

The definitive therapy for primary angle closure glaucoma is surgical.

Secondary Angle Closure Glaucoma

Pupillary block may develop from a swollen or dislocated lens or posterior synechiae (adhesions between the iris and lens). Secondary angle closure glaucoma, without pupillary block, can be caused by intraocular tumors, central retinal vein occlusion, or postoperatively. Treatment is directed at the offending cause.

ACUTE VISUAL LOSS

Differential Considerations

Acute visual loss, usually in only one eye, occurs over a period ranging from a few seconds to a day or two. The vision is generally reduced to 20/200 or worse. Patients need to be quickly evaluated to determine whether a treatable cause exists. The differential diagnosis of acute visual loss not related to trauma includes vascular occlusion, retinal detachment, vitreous hemorrhage, macular disorders, neuro-ophthalmologic disease, and hysteria. Most of these patients need ophthalmic or neurologic referral for a complete workup.

Patients may complain of acute visual loss when they may have neither an acute process nor a visual loss caused by the eye itself. For example, a patient with a visual field cut secondary to a neuro-ophthalmologic lesion may have an acute visual loss when the patient discovers the field cut. A patient with a hemianopsia usually has normal visual acuity even though both eyes are affected. An accurate history of how the patient discovered the visual loss, as well as the timing of that loss, is vital.

Clinical Features and Management

Central Retinal Artery Occlusion. Acute visual loss as a result of vascular occlusion of the central retinal artery is typically painless.

The ophthalmic artery is the first intracranial branch of the internal carotid artery and the central retinal artery is the first intraorbital branch of the ophthalmic artery. Central retinal artery occlusion causes an ischemic stroke of the retina. It occurs most commonly in those between 50 and 70 years of age, and 45% have carotid artery disease. Risk factors include hypertension, cardiac disease, diabetes, collagen vascular disease, vasculitis, cardiac valvular abnormality, and sickle cell disease. Patients with increased orbital pressure are also at risk, including patients with acute glaucoma, retrobulbar hemorrhage, and endocrine exophthalmos. Patients complain of a severe loss of vision that develops over seconds. Examination reveals a markedly reduced visual acuity with a prominent afferent pupillary defect. On funduscopic examination, the
Informative note 1: The retina is edematous with a pale gray-white appearance, and the fovea appears as a cherry-red spot (Fig. 69-22).

Therapy should be instituted immediately and should be directed at dislodging the embolus, dilating the artery to promote forward blood flow, and reducing intraocular pressure to allow an increase in perfusion gradient. Digital global massage should be begun immediately in the ED. Global massage is performed by applying direct digital pressure through closed eyelids. The pressure can be applied for 10 to 15 seconds and followed by a sudden release. Increases in carbon dioxide pressure (P\textsubscript{CO\textsubscript{2}}) lead to retinal artery vasodilation and increased retinal blood flow. Increases in P\textsubscript{CO\textsubscript{2}} are obtained by either rebreathing into a paper bag for 10 minutes each hour or inhaling a 95% oxygen, 5% carbon dioxide mixture (carbogen). Intraocular pressure may be reduced by instilling timolol maleate 0.5% topically. Acetzolamide, 500 mg IV or PO, lowers intraocular pressure as well as increases retinal blood flow. Emergent ophthalmologic consultation should be obtained as anterior chamber paracentesis may be attempted to facilitate the lowering of the intraocular pressure. One study, however, failed to find any therapeutic benefit for patients who received anterior chamber paracentesis and inhaled carbogen. One recent study showed improvement of visual acuity in 10 of 12 patients who were given IV tissue plasma activator for central retinal or ophthalmic artery occlusion. However, all of these patients had residual visual field defects. A complete medical evaluation is necessary because central retinal artery occlusion is usually an embolic event.

**Central Retinal Vein Occlusion.** A painless loss of vision, central retinal vein occlusion leads to edema, hemorrhage, and vascular leakage. The wide spectrum of clinical appearances depends on the degree of venous obstruction present. Loss of vision can range from minimal to recognition of hand motion only. There are two types of central retinal vein occlusion, ischemic and nonischemic. The nonischemic type involves mild fundus changes and does not have an afferent pupillary defect. These patients tend to have less severe visual loss, with two thirds of the patients having 20/40 or better visual acuity without therapy. Patients with ischemic central retinal vein occlusion have a marked decrease in visual acuity and often an afferent pupillary defect. Appearance can vary but classically includes dilated and tortuous veins, retinal hemorrhages, and disk edema. Hemorrhages can cover the entire fundus, giving a “blood and thunder” appearance (Fig. 69-23). Branch retinal vein occlusions occur just distal to an arteriovenous crossing, and hemorrhages occur distal to the site of occlusion. The differential diagnosis of central retinal vein occlusion includes hypertension, diabetes mellitus, hyperviscosity syndromes, and papilledema. All of these are bilateral processes, whereas central retinal vein occlusion is generally unilateral. Neovascular glaucoma is the major complication of ischemic central retinal vein occlusion. Treatment is complex and includes lowering of intraocular pressure, topical steroids, cyclotherapy, and photocoagulation. Underlying medical disease should be managed as well. The prognosis depends on the degree of obstruction and resultant complications.

**Retinal Breaks and Detachment.** The retina has two layers, the inner neuronal retina layer and the outer retinal pigment epithelial layer, which can be separated by fluid accumulation.

A retinal break is a tear in the retinal membranes and may or may not lead to retinal detachment. Retinal detachments occur by three mechanisms: rhegmatogenous, exudative, and tractional. Rhegmatogenous retinal detachment occurs as a result of a tear or hole in the neuronal layer, causing fluid from the vitreous cavity to leak between and separate the two retinal layers. Rhegmatogenous retinal detachment, the most common type of retinal detachment, generally occurs in patients older than 45 years, is more common in men than women, and is associated with degenerative myopia. Trauma may be associated with rhegmatogenous detachment by causing tears in the retina or by causing a disinsertion of the retina from its attachment at the ora serrata anteriorly. Traumatic retinal detachment can occur at any age. There is greater risk with severe myopia.

Exudative retinal detachment occurs as a result of fluid or blood leakage from vessels within the retina. Conditions leading to exudative retinal detachment include hypertension, toxemia of pregnancy, central retinal venous occlusion, glomerulonephritis, papilledema, vasculitis, and choroidal tumor.

Traction retinal detachment is a consequence of fibrous band formation in the vitreous and contraction of these bands. These fibrous bands result from the organization of inflammatory exudates or blood from prior vitreous hemorrhage. Typically, patients complain of flashes of light related to the traction on the retina, floaters related to vitreal blood or pigmented debris, and visual loss. The visual loss is commonly described as a filmy, cloudy, or curtain-like appearance. Pain is absent. Visual acuity can be minimally changed to severely decreased. Visual field cuts relate to the location of the retinal detachment, and an afferent pupillary defect occurs if the
detachment is large enough. When the detachment is visualized by ophthalmoscopy, the retina appears out of focus at the site of the detachment. In large retinal detachments with large fluid accumulation, the bullous detachment, with retinal folds, can easily be seen (see Fig. 69-12). Retinal detachment cannot be ruled out by direct funduscopy. Indirect ophthalmoscopy is needed to visualize the more anterior portions of the retina. Bedside ED ultrasonography has been shown to be helpful in confirming the presence of a retinal detachment.49

Acute rhegmatogenous and tractional detachment that threaten the fovea should be urgently surgically repaired.44 Acute retinal breaks are surgically repaired within 24 hours. All other acute rhegmatogenous and tractional retinal detachments can be repaired within a few days.44 Treatment of exudative detachment is aimed at the underlying cause or use of laser photocoagulation. Any patient suspected of having retinal break or detachment requires immediate ophthalmologic consultation.

Posterior Vitreous Detachment. Posterior vitreous detachment is a common occurrence in patients older than 60 years. With aging, the vitreous gel pulls away from the retina, which can lead to symptoms similar to those of retinal break, vitreous hemorrhage, and retinal detachment. No specific treatment is indicated for posterior vitreous detachment unless it is accompanied by a retinal break, vitreous hemorrhage, or retinal detachment.44 Patients with a new posterior vitreous detachment should have prompt evaluation by an ophthalmologist to rule out these surgically amenable complications.

Vitreous Hemorrhage. Vitreous hemorrhage results from bleeding into the preretinal space or into the vitreous cavity. The most common causes are diabetic retinopathy and retinal tears. Additional causes include neovascularization associated with branch vein occlusion, sickle cell disease, retinal detachment, posterior vitreous detachment, trauma, age-related macular degeneration, retinal artery microaneurysms, trauma, and intraocular tumor. Symptoms begin with floaters or “cobwebs” in the vision and may progress over a few hours to severe visual loss without pain. Direct ophthalmoscopy reveals a reddish haze in mild cases to a black reflex in severe cases. Details of the fundus are usually difficult to visualize. Vitreous hemorrhage by itself does not cause an afferent pupillary defect, which, if present, indicates a retinal detachment behind the vitreous hemorrhage. The hemorrhage may be evenly distributed throughout the vitreous or focal. Long-standing preretinal hemorrhage can become a white mass that may be misdiagnosed as a tumor, exudate, or infection. Initial therapy consists of bedrest with elevation of the head of the bed and avoidance of anticoagulative medications. Definitive therapy is targeted at the underlying cause. Vascular retinopathy is managed with laser photocoagulation or cryotherapy, and retinal tears and detachments are repaired. If the cause of the hemorrhage is unknown, prompt diagnostic workup is indicated to look for surgically correctable lesions. Ultrasonography can be used to determine whether a retinal detachment is present and may also determine the cause.49 Vitrectomy is indicated in certain patients.

Macular Disorders. Many disease processes cause acute changes in the macula leading to acute visual loss. The role of the emergency physician is to recognize the maculopathy and refer the patient to an ophthalmologist. Keys to the diagnosis of macular dysfunction include loss of central vision with preservation of peripheral vision, complaints of central visual distortion, and anatomic changes in the retina.

Degenerative maculopathies occur as the result of trauma, radiation exposure, inflammatory or infectious disease, vascular disease, toxins, or hereditary disease, or may be idiopathic in nature.

The most common form is age-related macular degeneration after the age of 65 years.71 It is a leading reason for legal blindness in the United States. Patients present with either a gradual or rapid onset of visual loss. Funduscopy reveals scattered drusen. Drusen are small, sharply defined yellow-white masses. Some patients with age-related macular degeneration and drusen develop a choroidal (subretinal) neovascular membrane, which appears as a grayish-green membrane beneath the retina. If this membrane is left untreated, hemorrhage, transudation, scar formation, or exudative detachment of the retina can result. If a large hemorrhage occurs from the neovascular membrane, it can cause severe central visual loss and may break through the retina into the vitreous, causing peripheral visual loss. Laser photocoagulation is the treatment for choroidal neovascular membrane formation and should be performed as soon as possible.71

Inflammatory processes involving the retina may also cause visual loss, especially if the macula is involved. Bacterial, viral, and protozoal agents have been shown to cause maculopathy. The presenting symptoms and signs vary according to the disease process and severity. Inflammatory debris from exudative processes may fill the vitreous, leading to a cloudy appearance. Infections within the eye are often associated with severe pain, redness, and periocular edema. If the retina and choroid are obliterated, the lesions appear white. Patients suspected of having an inflammatory maculopathy need emergent consultation and thorough medical evaluation.

Neuro-ophthalmologic Visual Loss. Visual loss not readily explained by an obvious abnormality on physical examination is called neuro-ophthalmologic visual loss. Patients can be divided into those who complain of decreased vision and have reduced visual acuity and those who complain of visual loss but have normal visual acuity. It is important to conduct careful visual field testing in the latter group.

Neuro-ophthalmologic visual loss can be further divided into prechiasmal, chiasmal, and postchiasmal anatomic areas.

Prechiasmal Visual Loss. Patients with prechiasmal disease have decreased visual acuity or visual field loss in the eye on the affected side. Prechiasmal disease may be a unilateral or bilateral process. The swinging flashlight test reveals an afferent pupillary defect on the side involved unless the process is bilateral. In such cases, the relative degree of afferent defect determines the results. Visual field testing demonstrates a field defect that does not respect the vertical meridian and is often localized to the center of the visual field. Causes of prechiasmal visual loss include optic neuritis, ischemic optic neuritis, compressive optic neuritis, and toxic and metabolic optic neuritis.

Optic Neuritis. Optic neuritis is an acute monocular loss of vision caused by focal demyelination of the optic nerve. The patients’ ages range from 15 to 45 years. Symptoms include a progressive loss of vision over several hours or days and ocular pain with eye movement. Visual acuity can range from minimal loss to no light perception. An afferent pupillary defect is always present, and direct ophthalmoscopic examination reveals a normal or swollen disk.75 The natural history of optic neuritis is for visual acuity to reach its poorest within 1 week and then slowly improve over the next several weeks. Approximately 30% of patients presenting with acute optic neuritis develop multiple sclerosis within 5 years.74 In an initial study of patients with acute optic neuritis, treatment with a 3-day course of IV methylprednisolone reduced the rate of development of multiple sclerosis over a 2-year period.74 However, 5-year follow-up of the same cohort of patients revealed no significant differences among treatment groups in the development of multiple sclerosis.75 Use of oral steroids for hastening optic neuritis is controversial. The Optic Neuritis Study Group...
showed an increased risk of optic neuritis recurrences in patients treated with oral prednisone.\textsuperscript{73,74} However, a randomized and controlled study of high-dose oral methylprednisolone in acute optic neuritis showed improved recovery from optic neuritis at 1 and 3 weeks but no effect at 8 weeks or on subsequent attack frequency.\textsuperscript{75} Long-term visual outcome is no different from that with observation alone.

**Ischemic Optic Neuropathy.** Ischemic optic neuropathy is the most common optic neuropathy and one of the most common causes of visual loss past middle age. Ischemic optic neuropathy can be giant cell arteritis or idiopathic. Temporal arteritis (giant cell arteritis) is characterized by weight loss, malaise, jaw pain, headache, scalp tenderness, polymyalgia rheumatica, low-grade fever, and severe painless visual loss. It is extremely rare in people younger than 50 years, but the incidence rises with each subsequent decade. A significant proportion of patients sustain visual loss, which can be sudden, severe, and bilateral.\textsuperscript{76} Occasionally, visual loss is preceded by episodes of amaurosis fugax. In one series of patients, visual loss was unilateral in 46\%, sequential in 37\%, and simultaneously bilateral in 17\%.\textsuperscript{77} There is a large afferent pupillary defect, visual loss, and a visual field defect that may respect the horizontal meridian. The optic disk shows pallor and swelling. The diagnosis can be aided with an elevated erythrocyte sedimentation rate (ESR), but can be seen with normal sedimentation rates.\textsuperscript{78} A guide to the upper limit of normal ESR is age/2 for men and (age + 10)/2 for women.\textsuperscript{79} The diagnosis is confirmed by temporal artery biopsy, although biopsy results have been normal early in the disease. Treatment for temporal arteritis should be instituted when typical signs and symptoms, particularly visual loss, exist. The standard treatment is high-dose corticosteroids, which should be started as soon as the diagnosis is suspected. Treatment should not wait for biopsy results. Biopsy should be performed within 1 week of diagnosis. Patients treated with oral prednisone were less likely to have visual improvement and more likely to develop fellow eye involvement than those receiving high-dose IV methylprednisolone.\textsuperscript{77} Patients with visual loss had a 34\% chance of improvement with IV methylprednisolone.\textsuperscript{77}

**Nonarteritic Ischemic Optic Neuropathy.** Nonarteritic ischemic optic neuropathy is much more common than temporal arteritis. These patients lack the classic symptoms of temporal arteritis and do not have an elevated ESR. Most of these patients have systemic vascular disease, diabetes, or hypertension, and they tend to be younger. They have painless visual loss, afferent pupillary defects, disk swelling, and visual field defects that respect the horizontal meridian. The visual loss is less severe than with temporal arteritis, and improvement occurs in one third of patients. Steroids have been advocated, but the results are unclear. If there is doubt about whether a particular patient has temporal arteritis or an idiopathic form of ischemic optic neuropathy, treatment with steroids should be started until a temporal artery biopsy is performed.

**Compressive Optic Neuropathy.** Compressive optic neuropathy occurs at any age and can be caused by tumor, aneurysm, sphenoid sinusitis or mucocele, blunt trauma, or thyroid disorders. Although defined as a prechiasmal disorder, compression can occasionally occur far enough posteriorly to affect the optic chiasm. Patients with compressive optic neuropathy have visual loss that continues to progress beyond 7 days. Compressive optic neuropathies require neuroradiographic evaluation and rapid medical and surgical intervention. Optic neuritis can be difficult to distinguish from a compressive optic neuropathy, but compressive syndromes tend to involve other cranial nerves. If the signs and symptoms do not closely fit optic neuritis or ischemic optic neuropathy, a compressive lesion exists until proved otherwise.

**Toxic and Metabolic Optic Neuropathy.** A large number of toxic and metabolic neuropathies exists. Common toxic causes include barbiturates, chloramphenicol, emetine, ethambutol, ethylene glycol, isoniazid, heavy metals, and methanol. Causes of metabolic optic neuropathies include thiamine deficiency and pernicious anemia. These processes are bilateral, progressive, and symmetrical. Visual loss can be severe, and visual field testing reveals central defects. Treatment is aimed at the underlying toxin or metabolite involved.

**Chiasmal Visual Loss.** Chiasmal disease is the second category of neuro-ophthalmologic visual loss, most commonly caused by chiasmal compression from pituitary tumors, craniopharyngioma, or meningioma. Visual loss is gradual and progressive. Although formal visual field testing is necessary to stage the condition, the diagnosis can usually be made by confrontation visual field testing. The classic defect is a bitemporal hemianopsia; however, tumors often compress the optic chiasm and optic nerves asymmetrically, resulting in combined central and temporal defects. When a visual field defect respects the vertical meridian from a neuro-ophthalmologic visual loss, the lesion is out of the globe and must be either chiasmal or postchiasmal.

**Postchiasmal Visual Loss.** Postchiasmal disease represents the third category of neuro-ophthalmologic visual loss. The most common causes are infarction, tumor, arteriovenous malformation, and migraine disorders. Patients complain of difficulty in performing a certain task, such as reading. Lesions can be located from the immediate postchiasmal optic tract to the occipital cortex. The classic visual field defect is homonymous hemianopsia. Patients with such lesions have a focal neurologic deficit and need neurologic consultation. Cortical blindness is a special cause of neuro-ophthalmologic visual loss that is most commonly caused by bilateral occipital infarction. Cortical blindness is often mistaken for functional blindness because patients have both normal funduscopic examinations and intact pupillary reflexes. Antón's syndrome is characterized by bilateral blindness, normal pupillary reflexes, bilateral occipital lesions, and, interestingly, denial of blindness. It is this denial of blindness that may be incorrectly assumed to be evidence for a functional process.

**Functional Visual Loss.** Patients with functional visual loss fall into two categories: hysterical conversion reactions and malingering. Patients with hysterical conversion reactions have a non-deliberate, imagined visual loss. The patient has a flatter affect than one would expect under the circumstances of acute visual loss. The patient might appear completely unaffected emotionally by the acute visual loss. The malingerer, on the other hand, is a patient who is well aware that no visual loss exists, yet deliberately feigns visual loss for secondary gain. This patient is typically overemotional concerning the visual loss.

Examination of a patient with a suspected functional visual loss should be conducted in the same manner as every other ophthalmologic examination, with particular attention to possible neuro-ophthalmologic deficits. Normal pupillary reflexes and the absence of an afferent pupillary defect, together with a normal funduscopic examination, point toward functional visual loss. Multiple tests can ascertain whether a visual loss is organic or functional. Patients with feigned visual loss are hesitant to try to appose the index fingers of each hand and often write their names in a disorderly fashion, whereas genuinely blind patients can sign their names without difficulty. One effective test involves placing a large mirror directly in front of the patient's face and asking the patient to look straight ahead. The mirror is then tilted slightly back and forth. Most patients follow the reflection of their eyes in the mirror as it changes position, proving feigned visual loss. Another test commonly used is the optokinetic nystagmus (OKN) drum.
The drum should be turned in front of the patient’s open eyes. If the patient is properly seeing, the eyes will automatically follow the stripes of the drum. Some difficult cases require more sophisticated tests. Definitive treatment of functional visual loss should include a collaborative effort by the emergency physician, ophthalmology, and psychiatry. If the diagnosis of feigned visual loss cannot be definitively made, consultation is required to rule out neuro-ophthalmologic visual loss.

**ANISOCORIA**

**Clinical Features**

Anisocoria in a patient with head trauma or decreased level of consciousness requires immediate and aggressive evaluation and intervention because it may result from increased intracranial pressure. If a patient is awake and alert, has no signs of trauma, and has anisocoria of unknown cause, less urgency exists. The first step is to determine which pupil is abnormal. If one pupil constricts poorly to a light stimulus, it is likely to be the abnormal one. Anisocoria greater in dark suggests that the abnormal pupil is the smaller pupil, whereas anisocoria greater in light suggests that the abnormal pupil is the larger pupil. If anisocoria exists in a patient with a normal afferent visual system, either an innervational or structural defect in the iris sphincter exists. Most structural defects in the iris can be diagnosed by slit-lamp examination. If both pupils react well to light and no iris abnormalities are seen with slit-lamp examination, the next step is to determine whether the anisocoria increases in light or darkness. Adie’s tonic pupil, pharmacologic blockade, and third-nerve palsy are associated with anisocoria that increases in light, whereas benign anisocoria and Horner’s syndrome are associated with anisocoria that increases in darkness. Comparing pupillary size in a brightly and dimly lit room is the easiest method to evaluate the effect of lighting on anisocoria.

**Adie’s Tonic Pupil**

With Adie’s tonic pupil, patients complain of blurred near vision but have normal distant vision. Adie’s syndrome is seen in young women 70% of the time and has associated symmetrically reduced deep tendon reflexes. Examination reveals poor accommodation with a very slow constriction to near testing. The pupil redilates slowly when the vision is again made distant. Slit-lamp examination reveals sector palsies of the iris. The diagnosis is confirmed when a weak cholinergic agent (pilocarpine 0.1%) causes an intense pupillary constriction as a result of cholinergic supersensitivity in the affected pupil compared with the normal pupil. These patients need to be referred to an ophthalmologist on a nonemergent basis for cholinergic agent therapy.

**Pharmacologic Mydriasis**

Pharmacologic mydriasis can be caused by deliberate or inadvertent local administration of both sympathomimetic and parasympatholytic agents. Phenylephrine and cocaine are two sympathomimetic substances commonly used as a nasal premedicant for nasotracheal intubation; careless administration may lead to anisocoria. Parasympatholytic agents, such as atropine and scopolamine, have been implicated in the development of anisocoria. The transdermal scopolamine patches placed for the prevention of motion sickness can cause anisocoria. Pilocarpine 1.0% can be used in special circumstances to help differentiate a third-nerve palsy from pharmacologically mediated mydriasis. The administration of pilocarpine 1.0% rapidly constricts the pupil that is dilated secondary to a third-nerve palsy but does not produce miosis in a pupil dilated from anticholinergic agents.

**Third-Nerve Palsy**

Patients with anisocoria that increases in light, without evidence of Adie’s tonic pupil or pharmacologic medication, should be suspected of having a third-nerve palsy. They almost always have other signs of third-nerve involvement, including ptosis and extraocular muscle dysfunction. Patients complain of diplopia, and the involved eye is turned down and out. Patients may have ptosis and extraocular dysfunction with or without pupil dilatation. Any patient who has a new-onset third-nerve lesion involving the pupil should be admitted to the hospital to rule out aneurysm.

**Horner’s Syndrome**

Horner’s syndrome consists of ptosis, miosis, and facial anhidrosis resulting from an interruption of sympathetic innervation. The dilatation lag, a classic finding, results from the Horner’s pupil requiring up to 15 seconds to dilate fully. The anisocoria is greater at 3 to 5 seconds of darkness than at 15 seconds of darkness, although the anisocoria is still more pronounced than in light. Topical ophthalmologic cocaine 10% can be used to aid the diagnosis. A Horner’s pupil dilates less than a normal pupil in reaction to topical cocaine. Central nervous system strokes and tumors, lung carcinomas, thyroid adenomas, Pancoast’s tumors, headache syndrome, carotid dissection, herpes zoster, otitis media, and trauma to brachial plexus during delivery are all causes of Horner’s syndrome. Hydroxyamphetamine 1% administered 24 hours after the cocaine test can be used to determine the level of sympathetic interruption and dictate the type of workup indicated. In general, patients with new-onset Horner’s syndrome should receive a thorough and immediate workup to determine the etiology.

**Physiologic Anisocoria**

Twenty percent of the population may have anisocoria of greater than 0.4 mm at any given examination. This anisocoria may be transient or prolonged and may alternate pupils. Although the anisocoria increases in darkness, there is no dilatation lag as seen with Horner’s syndrome. No associated features, such as loss in vision and diplopia, are seen and no further treatment is required.

**ABNORMAL OPTIC DISK**

**Clinical Features and Differential Considerations**

An important acquired cause of an abnormal optic disk is papilledema. Papilledema refers to the changes in the optic disk from increased intracranial pressure. The subarachnoid space of the brain is continuous with the optic nerve sheath. Any increase in the cerebrospinal fluid pressure can be transmitted to the optic nerve, resulting in swelling of the optic nerve head. Causes include intracranial tumor, pseudotumor cerebri, intracranial hematomas from trauma, subarachnoid hemorrhage, brain abscess, and meningitis or encephalitis. There is swelling of the optic disk and blurring of the disk margins, hyperemia, and loss of physiologic cupping (Fig. 69-24). There may be obliteration of spontaneous venous pulsations.
Flame-shaped hemorrhages and yellow exudates appear near the disk margins as the edema progresses. Patients may have significant headaches or be completely asymptomatic. Visual acuity is not affected until the papilledema is long standing. Brief obscurations of vision, enlargement of the physiologic blind spot, and inferior nasal visual field loss are common. Papilledema is a bilateral process but may be asymmetrical. A patient with newly diagnosed papilledema should receive immediate neuroradiographic evaluation.

Many conditions may mimic papilledema, including central retinal vein occlusion, papillitis, hypertensive retinopathy, ischemic optic neuritis, optic disk vasculitis, and diabetic papillitis with retinopathy.

## NYSTAGMUS

### Clinical Features and Differential Considerations

Clinically significant nystagmus is an oscillation of the eyes that occurs within 30 degrees of the midline. Pendular nystagmus is of equal velocity in both directions. With jerk nystagmus, the velocity is faster in one direction. The pathologic component is the slow movement, but the nystagmus is named according to the direction of the fast component. Nystagmus can also be divided into monocular or binocular, conjugate (both eyes moving in the same direction), or disconjugate (eyes moving in opposite directions), and primary gaze position or gaze position nystagmus. Important questions include the presence of tinnitus, nausea, vomiting, oscillopsia, and vertigo.

Congenital nystagmus is noted at birth or within the perinatal period and is usually horizontal, conjugate, bilateral, symmetrical, and pendular. On lateral gaze, this nystagmus may become jerky in nature but remains horizontal despite upward or downward gaze. Congenital nystagmus is damped by convergence, increased with fixation, accentuated by covering one eye, and abolished with sleep. These patients do not have oscillopsia, nor do they have other neurologic complaints. Almost all of these patients have recognized their nystagmus previously, and the diagnosis is generally straightforward.

There are many causes of acquired nystagmus. General categories of disease that result in nystagmus include toxic exposure, defective retinal impulses, diseases of the labyrinths or of the vestibular nuclei, and lesions of the brainstem or cerebellum controlling ocular posture. The workup includes drug and toxic screening and neuroradiologic testing with a CT or MRI scan.

### DISORDERS OF EXTRAOCULAR MOVEMENT

#### Clinical Features and Differential Considerations

Patients complain of diplopia produced or exacerbated by certain eye movements. A knowledge of the anatomy of the extraocular muscles is useful (Fig. 69-25). The first step is to determine whether the diplopia is monocular or binocular. Binocular diplopia disappears with either eye covered. Monocular diplopia is less concerning, caused most commonly by refractive errors, a dislocated lens, iridodialysis, or feigned disease.

Binocular diplopia from misalignment of the eyes has a multitude of causes. Local mechanical defects such as hematoma, orbital floor fractures, or abscess and palsy of cranial nerve III, IV, or VI can lead to motility problems. Thyroid disease, progressive ophthalmoplegia, extraocular muscle fibrosis syndrome, multiple sclerosis, and myasthenia gravis can all lead to newly acquired extraocular movement dysfunction.

The most common cause is cranial nerve palsy. Patients with brainstem disease often have involvement of other cranial nerves, disturbances in level of consciousness, and sensorimotor loss. Isolated third-nerve lesions produce a palsy in which the patient develops ptosis, an inability to turn the eye inward or upward, and pupillary mydriasis. The causes of third-nerve palsy are varied and require aggressive and immediate neurologic and radiologic examination.

Isolated fourth-nerve palsy is an easily missed disorder. Patients complain of double vision, which is made worse in downgaze, or gaze away from the paretic side. These patients typically have a head tilt to the opposite shoulder to compensate for the vertical extorsion and have weakness in downward gaze. Trauma and vascular disease account for most cases of isolated fourth-nerve palsy, but aneurysm, intracranial tumor, and myasthenia gravis have been implicated.

Sixth cranial nerve palsies are the most commonly reported ocular motor palsies. Patients with sixth cranial nerve palsies have an esotropia that is worsened by lateral gaze and often turn their heads laterally toward the paretic side to compensate. Sixth-nerve palsy is caused by a variety of diseases. Wernicke-Korsakoff syndrome, aneurysm, vascular disease (diabetes, hypertension, atherosclerosis), trauma, neoplasm, multiple sclerosis, meningitis, thyroid eye disease, and increased intracranial pressure may all cause dysfunction. Workup consists of careful neurologic and radiologic examination.

MANAGEMENT

Ophthalmic Drugs

General Considerations

Most ocular medications are administered as drops, which have the advantage of concentrating drug delivery to the anterior segment of the eye and reducing unwanted systemic side effects. Eye drops have the additional advantages of rapid absorption, brief effect, and minimal interference with the visual media.

Unfortunately, the eye retains only a small amount of the drug; the remainder is cleared by the rapid turnover of tears.

To improve absorption, patients who are taking more than one eye drop should ideally wait 10 minutes between drops to prevent the second drop from washing out the first. Patients should apply digital pressure at the medial canthus of the eye to prevent drainage of drug through the nasolacrimal duct and keep their eyes closed for several minutes after instilling their drops to halt the lacrimal pumping mechanisms. Ointments increase the contact time of the medication with the anterior segment of the eye. Ointments blur vision but provide a pleasant lubrication to the eye that has been traumatized and patched and do not seem to interfere with corneal wound healing.

Drug Classification

Ophthalmologic medications can be classified into several categories, including anesthetics, antibiotics, antivirals, corticosteroids, and others. The emergency physician should be familiar with some common agents that are part of these categories and should be familiar with indications of each type of medication.

Local anesthetics block neurotransmission along sensory nerve fibers. Ocular procedures facilitated by topical anesthetics include direct inspection, foreign body removal, irrigation, tonometry, and contact lens removal. Local anesthetics inhibit wound healing, and severe keratopathy can result from indiscriminate use of topical anesthetics. Local anesthetic drops should not be prescribed as pain medicine for self-administration by patients.

Antibiotics and antiviral agents are commonly prescribed. The choice of antibiotic agent should be guided by culture, Gram’s stain, or suspected bacteria or virus. Antiviral agents are generally prescribed after consultation with an ophthalmologist.

Corticosteroids are used by ophthalmologists for many ocular conditions, but their use by emergency physicians should be limited. Corticosteroids can accelerate the activity of herpes simplex virus and should not be given to a patient when the diagnosis is uncertain. Post-traumatic iridocyclitis is one of the few conditions in which an emergency physician might consider prescribing a topical steroid agent, but close follow-up with an ophthalmologist is highly recommended.

Cycloplegics block the muscarinic receptors, producing paralysis of the ciliary muscle, which always causes mydriasis. Cycloplegics are useful in relieving pain and photophobia secondary to ciliary spasm related to corneal abrasion, ocular trauma, and iridocyclitis. Mydriatics dilate the pupil, but not all mydriatics are cycloplegics. Mydriatics are contraindicated in any patient with a history of glaucoma, evidence of increased intraocular pressure, presence of a shallow anterior chamber, suspicion of a ruptured globe, or if a lens implant is present. Atropine has a long duration of action (1–2 weeks) and should be prescribed only by an ophthalmologist. Decongestants and antiallergy ocular medications are commonly prescribed and lessen allergic ocular symptoms.

A number of agents are used to treat glaucoma. It is important to know that these are absorbed and can have systemic effects. For example, topical beta-blocker agents can result in symptomatic bradycardia or increased bronchospasm.

Nonsteroidal anti-inflammatory agents are useful in alleviating the symptoms of inflammation in a wide variety of ocular conditions and provide symptomatic improvement in corneal abrasions.

Artificial tears relieve symptoms related to dry eyes and protect the corneas of unconscious patients as well as patients suffering from Bell’s palsy.

KEY CONCEPTS

- Orbital floor fractures: Surgical repair is only for persistent diplopia or cosmetic concerns and is generally not performed until swelling subsides in 7 to 10 days. CT scan is the imaging choice.
- Retrobulbar hematoma: When a retrobulbar hematoma compromises retinal circulation, immediate treatment of increased intraocular pressure includes carbonic anhydrase inhibitor, topical beta-blocker, and IV mannitol. A lateral canthotomy can be done in the ED as a temporizing measure before definitive decompression.
- Corneal abrasions: Data suggest that eye patching confers no benefit in healing small, uncomplicated corneal abrasions.
- Globe rupture: Treatment includes avoidance of further examination or manipulation and placement of a protective metal eye shield to prevent accidental pressure on the globe. Antiemetics should be given if nausea is present. Broad-spectrum IV antibiotics should be instituted.
- Retinal detachments: Retinal tears or detachments do not cause pain. Examination may reveal the hazy gray membrane of the retina billowing forward, but many tears are peripherally located and not seen with direct ophthalmoscopy. Visual acuity may be normal unless the macula is involved. Indirect ophthalmoscopy is warranted if historical clues to the presence of retinal tears are present.
- Bacterial conjunctivitis: In uncomplicated acute bacterial conjunctivitis, neomycin ophthalmic solutions should be avoided because of the high incidence of hypersensitivity reactions. Corticosteroids and eye patching should be avoided.
- Glaucoma: Attacks of primary angle closure glaucoma produce symptoms that are abrupt in onset and include severe eye pain, blurred vision, headache, nausea, vomiting, and occasionally abdominal pain. Signs include conjunctival injection and a cloudy (steamy) cornea with a midpositioned to dilated pupil that is sluggish or fixed. Intraocular pressures are markedly elevated.
- Topical anesthetics: These should not be prescribed for painful eye disorders as prolonged use may result in corneal ulcer formation.

OTITIS MEDIA

Perspective

Background

Otitis media (OM) is the most common diagnosis made by U.S. physicians for children younger than 15 years old. In 2002, 16.7 million visits were made to physician offices across the country for OM with an estimated 2.65 million visits made to emergency departments (ED), making it the sixth most common ED discharge diagnosis. Over 80% of children will have at least one episode of acute otitis media (AOM) during their lifetime, and by age 3 up to 40% will have at least three episodes during the first 3 years of life. The financial repercussions are enormous; one estimate is that $5 billion per year is spent on the evaluation, treatment, and socioeconomic effects of OM. The most frequent outpatient use of antimicrobials in the United States is for OM, with the number of prescriptions increasing from 12 million in 1980 to more than 23.6 million in 1992.

Epidemiology

Male gender, day care attendance, parental smoking, pacifier use, and a family history of middle ear disease have been implicated as risk factors. Children with anatomic abnormalities, such as cleft palate and Down syndrome, have a higher rate of OM, probably because of eustachian tube abnormalities. Some immunocompromised patients, including patients with HIV, may have recurrent OM as an initial symptom of their underlying disease. OM and upper respiratory infections occur primarily in the winter. Breast-feeding seems to be protective.

Definitions

Otitis media is broadly defined as inflammation of the inner ear and is a continuum of disease. Acute otitis media is defined as the signs and symptoms of an acute infection, with evidence of effusion; this has also been called acute suppurative, or purulent, OM. Otitis media with effusion (OME) has effusion without signs or symptoms of an acute infection; additional descriptive terms include serous, mucoid, nonsuppurative, or secretory OM. OME is classified further into acute (<3 weeks), subacute (3 weeks to 3 months), and chronic (>3 months). Chronic OM, or chronic suppurative otitis media, refers to chronic discharge from the ear through perforation of an intact membrane. Recurrent OM is defined by three or more episodes over 6 months or four episodes in 1 year.

Principles of Disease

Pathophysiology

Eustachian tube dysfunction is the central theme of most theories of AOM pathogenesis. The eustachian tube, between the middle ear cavity and the nasopharynx, ventilates the middle ear to equilibrate pressure, allows for middle ear drainage, and provides protection from nasopharyngeal secretions. In children, it measures approximately 18 mm and is almost horizontal. As individuals age, the eustachian tube widens, doubles in length, becomes more vertically oriented, and stiffens (which may explain the decreased incidence of AOM in adults). Normally, the tube is collapsed, but it opens during yawning, chewing, and swallowing.

The eustachian tube may become either mechanically or functionally obstructed, decreasing middle ear ventilation. Examples of mechanical obstruction include inflammations from an upper respiratory infection, hypertrophied adenoids, and a cleft palate. Functional obstruction from persistent tubal collapse occurs primarily in young children, who have less fibrocartilage support of the medial eustachian tube than older children or adults. It has been postulated that this dysfunction results in negative middle ear cavity pressure, causing a transudate of fluid that combines with the reflux of nasopharyngeal secretions and bacteria.

Etiology

The most common causes of bacterial infection in children are Streptococcus pneumoniae, Haemophilus influenzae (primarily non-typeable), and Moraxella (Branhamella) catarrhalis. Streptococcus pyogenes, Staphylococcus aureus, and gram-negative bacteria are much less common. Adult infection involves similar organisms. In OME, there is a greater proportion of H. influenzae and a higher percentage of sterile effusions. Viruses also have been found in the middle ear aspirates of children with OM and are found in anywhere from 5 to 16%. The advent of reserve transcriptase polymerase chain reaction technology for viral identification has improved, and it is likely that an even greater number of viral agents will be found. Some authors believe that viral infection is the cause of the inflammatory reaction in most cases and antibiotics are not necessary.
virus is the most common virus, but parainfluenza, influenza, enterovirus, rhinovirus, and adenovirus have also been found in the middle ear aspirates of children.10,11 Viruses have contributed to poor treatment outcome by increasing middle ear inflammation, decreasing neutrophil function and decreasing antibiotic penetration into the middle ear.14

In young children, it was believed that gram-negative organisms and S. aureus were the causative organisms. Although these bacteria may be the causes in intubated patients or patients in the neonatal intensive care unit, healthy newborns tend to be infected by the same pathogens as healthy older children.15 Bullous myringitis presents with bullae on the tympanic membrane and may be present in up to 5% of cases of OM in children less than 2 years.16 Although previously thought to be caused by Mycoplasma pneumoniae, culturing middle ear aspirates in this condition generally grows the usual organisms that cause AOM and M. pneumoniae is uncommon.16,17

Over 70% of children presenting with purulent conjunctivitis may have OM, a symptom complex described as the otitis-conjunctivitis syndrome,18 which is predominantly caused by H. influenzae.19 Other, less likely organisms that can cause AOM include Mycobacterium tuberculosis (primarily in children) and Chlamydia trachomatis (most commonly seen in children younger than 6 months old with pneumonia).20

Conjugate pneumococcal vaccine has been effective in markedly reducing invasive disease in young children and decreasing the incidence of OM.21 It is estimated that its use would decrease the number of visits to the pediatrician for OM by 1 million, and the number of children receiving tympanostomy tubes might decrease by 500,000.22 The vaccine may be responsible for an increase in gram-negative and virulent β-lactamase-producing organisms in middle ear effusions, primarily in patients who have recently been treated.23,24

Up to 5 to 10% of the general pediatric population may be at risk for developing four or more episodes of OM in the first year of life; these children are generally called otitis-prone.26 They may have subtle immunologic abnormalities or a greater baseline colonization of virus and bacteria than the general population.27

**Clinical Features**

OM may be manifested by a multitude of symptoms, such as cough, poor appetite, diarrhea, vomiting, fever, and pulling at ears, all of which are nonspecific. Older children may be able to verbalize pain, but otalgia is not universally present. In OM, pain usually precedes otorrhea, in contrast to OME, in which pain accompanies the drainage. Children often have associated upper respiratory tract infections. Fever may be present, but in one large series, a temperature of 38.3°C or greater was present in only 26% of the episodes, with only 4% having a fever of 40°C or greater.28 Some authorities have modified the definition to include otoscopic findings of acute inflammation regardless of symptoms; with this definition, one third of cases are not accompanied initially by acute symptoms.29

The auricle and external canal should be inspected for signs of erythema, discharge, or tenderness. If the canal is occluded with cerumen, an ear curette with direct visualization may be successful in clearing the canal. If not, the placement of 3% hydrogen peroxide or emulsifying drops, followed by gentle irrigation, may cleanse the canal.

The tympanic membrane (TM) may be bulging (as in AOM), neutral, or retracted as seen in chronic OME.30 The color may be red, pink, yellow, or a normal pearly gray or translucent. The presence of erythema in itself does not indicate infection because crying or fever may cause hyperemia; however, a TM that is distinctly red (defined as hemorrhagic, strongly or moderately red) suggests AOM.30

Landmarks that should be visible include the pars flaccida, the malleolus, and the light reflex below the umbo.30 The TM may have air-fluid levels, may have bubbles behind the TM, or may be completely opacified, all of which indicate middle ear effusion. The lack of mobility is one of the most sensitive indicators of middle ear effusion. In fact, mobility in response to insufflation should raise serious doubt as to the diagnosis of AOM. A TM that is cloudy, bulging, and distinctly immobile indicates AOM.30 In OME, the TM is often retracted, with the malleolus being particularly prominent. The landmarks all may be obscured in the presence of significant fluid. A comparison examination of the other ear may help in confirming suspected infection.

In neonates, the TM appears thickened and opaque normally in the first few weeks of life, and the TM is in a highly oblique position. With tympanostomy tubes, in the absence of infection, the TM may have decreased mobility, altered landmarks, opacity, or dullness. If the tube is patent, erythema and discharge may indicate infection. If not, erythema, bulging of the TM, and immobility indicate AOM.

**Complications**

Before the use of antibiotics, there was a 20% incidence of complications from AOM, with mastoiditis and otic meningitis being relatively common.31 Complications are either intratemporal or intracranial, occurring in both adults and children. The development of either complication of OM is thought to occur by one of three mechanisms: (1) direct extension of infection through bone weakened by osteomyelitis or cholesteatoma; (2) retrograde spread of infection by thrombophlebitis; or (3) extension of infection along preformed pathways, such as the round or oval windows or through dehiscences that are the result of congenital malformations.32 The use of antibiotics has led to a reduction of all complications to less than 1%.33

**Intratemporal.** Hearing impairment is the most common complication in OM. Almost all children with OM have a temporary conductive hearing loss; sensorineural deficit occurs less commonly, probably as a spread of infection through the round window. This deficit may contribute to the association of OM with decreased or delayed speech, language, or cognitive development.

TM perforation occurs most commonly at the pars tensa and usually resolves spontaneously. It may persist for a longer period, resulting in a chronic perforation, chronic OM, or both.20 Chronic OM refers to inflammation of the middle ear that persists for 6 weeks or longer accompanied by discharge through perforation of an intact membrane. It may occur spontaneously or through tympanostomy tubes. The pathogenesis is multifactorial, and the most commonly involved causal organisms are Pseudomonas aeruginosa, S. aureus, gram-negative organisms, and anaerobes. Whereas acute otitis and its complications are more common in younger children, complications secondary to chronic OM are more common in older children and adults.33 Topical antibiotics are an effective treatment.26 Systemic treatment should be reserved for patients showing signs of complicated or invasive infections or signs of systemic disease.24 Cholesteatoma is an accumulation of keratin-producing squamous epithelium in the middle ear and may result in erosion of bone within the middle ear cavity. It is seen most often in OME, in which retraction of the TM is a common problem and its presence may alter the courses of some treatment therapies.

Labyrinthitis occurs when infection spreads to the cochlear and vestibular apparatus, usually through the round or oval
windows. Serous labyrinthitis results when bacteria from the middle ear spread into the labyrinth space, resulting in a mixed conductive-sensorineural hearing loss and vestibular symptoms. Suppurative labyrinthitis is the development of purulence directly into the labyrinth as a result of bacterial invasion through the round window or around the annular ligament of the round window. It generally begins suddenly with mixed hearing loss and vestibular symptoms and is generally more severe than the serous form.32

The facial nerve courses through the middle ear, and facial paralysis is a known complication in OM. The exact mechanism is unknown, but it may be due to infection, surrounding osteitis, facial nerve swelling, demyelination of the facial nerve from bacterial toxins, or facial nerve ischemia.37 Infectious eczematoid dermatitis may result from the otorrhea of OM, with perforation or tympanostomy tubes infecting the external auditory canal. Treatment involves otic suspension (not solution). Although caution is urged with these products, the incidence of adverse effects is small.38

Intracranial. Meningitis is the most common intracranial complication for AOM, resulting from hematogenous spread and direct invasion. Brain abscesses are most commonly due to chronic otitis and are the second most common intracranial complication.39 They generally result from hematogenous extension secondary to thrombophlebitis but can result from erosion as well.35 Causative organisms include Proteus, Pseudomonas, Staphylococcus aureus, Streptococcus pneumoniae, and anaerobes.40,41 Symptoms include headache, fever, vomiting, and mental status changes.

An extradural abscess may result from destruction of bone adjacent to the dura by cholesteatoma, infection, or both. Subdural empyema is a collection of fluid between the dura and arachnoid membrane as a result of infection or venous thrombophlebitis. Focal otic encephalitis is an edematous or inflamed area in the brain from a complication of OM, extradural abscess, or sinus dural thrombophlebitis.

Lateral venous sinus thrombosis occurs when the mastoid infection comes in contact with the sinus wall, which inflames the adventitia and penetrates the venous wall. Thrombosis and embolization occur. The classic presentation is the presence of high spiking fevers in a “picket fence” pattern, chills, earache, headache, and mastoid and neck tenderness.

Antibiotics are the primary treatment for all complications of OM. Myringotomy with or without tympanostomy tube placement ensures drainage of the middle ear and makes specimens available for culture.42 Operative treatment may be required in the presence of intratemporal complications with abscess formation or intracranial complications, or when chronic OM or cholesteatoma is a cause of the acute complications.42,43

Diagnostic Strategies

Pneumatic otoscopy to confirm immobility of the TM is an important part of diagnosis in all cases (see earlier discussion). Tympanocentesis is aspiration of the middle ear effusion to identify causative organisms and is rarely indicated in the ED. Indications include patients with AOM who are seriously ill or appear toxic, are unresponsive to therapy, are younger than 4 weeks old, are immunocompromised, are receiving antimicrobials, or have suppurative complications.

Differential Considerations

OM usually does not cause a significantly high fever; in approaching a febrile, ill-appearing infant, the physician should investigate other causes for the fever. If a child or adult complains of otalgia, additional considerations or possibilities include OME, trauma, foreign bodies, and complications of OM such as mastoiditis. Ear pain also may be referred from the teeth, sinuses, throat, or temporomandibular joint.

Management

Although more than 16 antibiotics have been approved by the Food and Drug Administration for OM, few have shown efficacy against all of the main causative pathogens.4 Concern about the rising rates of antibacterial resistance and the growing costs of antibacterial prescriptions has focused the attention of the medical community and the general public on the need for judicious use of bacterial agents.44 Based on this and other factors, the American Academy of Pediatrics, the American Academy of Family Physicians, the Agency for Healthcare Research and Quality, and the Southern California Evidence Based Practice Center met to develop guidelines for the diagnosis and management of AOM to assist physicians in providing a framework for clinical decision making. These guidelines apply specifically to an otherwise healthy child between the ages of 2 months and 12 years without underlying conditions that may alter the natural course of acute AOM (Table 70-1).4

Making a diagnosis of AOM requires three findings: (1) history of acute onset, (2) signs of middle ear effusion (including TM immobility), and (3) signs or symptoms of middle ear inflammation (see Table 70-1).

Because over 80% of cases of AOM resolve spontaneously,45 the use of observation versus antibiotics has been advocated.46 Several European countries have practiced this approach of “watchful waiting” for 48 hours for a number of years, with a resulting lower rate of antibiotic-resistant bacteria.47 Although somewhat controversial, this approach has been met with acceptance by a majority of patients and physicians.47,48 It has been successful in an ED setting49 but has not yet become standard practice.50

The decision to treat is based on the age of the patient and certainty of the diagnosis.44 The guidelines recommend an age-stratified approach that incorporates the age with a combination of diagnostic certainty and illness severity. Observation is an option in children older than 2 years, unless the child has severe otalgia or temperature of 39° C or greater (Table 70-2). In children 6 months to 2 years old, treatment recommendations are based on the certainty of the diagnosis and severity of illness, with recommended observation if the diagnosis is uncertain. The guidelines recommend treatment in children younger than 6 months old. Observation recommendations are based on the degree of severity, reliability of the caregivers, and ability for close follow-up. If there is concern about the ability to get follow-up, parents can be given a prescription to be filled if the patient does not improve in 48 hours—a so-called safety net.51

There is evidence that immediate antibiotic therapy for children younger than 2 years with severe symptoms results in a more rapid resolution of symptomatic disease and a reduced rate of treatment failure or relapse.52,53 The potential risk of complications must be balanced against the side effects of antibiotic use, which may include allergic reactions, gastric upset, accelerated bacterial resistance, and unfavorable changes in the bacterial flora.54

Amoxicillin’s cost, efficacy, safety profile, and palatability continue to make it a good first-line agent. It can be given twice a day at a dosage of 80 to 90 mg/kg/day. This higher concentration is effective against susceptible and intermediate resistant strains of Streptococcus pneumoniae. In patients who are allergic to penicillin, the guidelines distinguish between those
Antibacterial therapy

Clinical Antibacterial therapy

CERTAIN UNCERTAIN Part Medicine and Surgery / Section One

If treatment failure occurs within the first 28 days, observational follow-up is appropriate. Patients with a history of vomiting, poor compliance, or a lack of symptoms, such as ear pain; fever; and TM findings of redness, may exhibit OME, but 90% of cases resolve within 3 months. Patients who have been on antibiotics in the prior month should receive high-dose amoxicillin, high-dose amoxicillin-clavulanate, or cefuroxime axetil as the initial treatment. Cefdinir may be preferred over cefuroxime because of its more pleasing taste, which can equate to improved compliance. Treatment failures at 3 days should be treated with intramuscular ceftriaxone or clindamycin, with tympanocentesis strongly encouraged. Clindamycin should be used only for treatment of S. pneumoniae because it is not effective against either H. influenzae or M. catarrhalis. Treatment failures within 1 month should be treated with high-dose amoxicillin-clavulanate, cefuroxime axetil, or intramuscular ceftriaxone.

Trimethoprim-sulfamethoxazole and macrolides traditionally have been second-line agents, but resistance is increasing—40% for trimethoprim-sulfamethoxazole and 30% for macrolides. In addition, there is substantial cross-resistance between these drugs and the β-lactams, resulting in further treatment failures in children finishing a course of amoxicillin. Fluoroquinolones may be effective, but their use in children is not approved.

Response to antibiotics is only one of a number of factors that affect clinical outcome. Other factors include impairment of endothelin [ET] function, co-infection with nonbacterial pathogens, and host immune response. Local practice patterns and antimicrobial sensitivities may also play a role in the types of treatment given. Other antibiotics available for treatment include erythromycin-sulfisoxazole, azithromycin, clarithromycin, cephalexin, cefaclor, cefprozil, loracarbef, cefdinir, cefixime, cefpodoxime, and cefditoren. These were not included in the Centers for Disease Control and Prevention guidelines primarily because there was a lack of data on their efficacy.

Treatment historically involved a 10-day course. Numerous studies have compared traditional treatment courses with shorter therapy, which is most appropriate for uncomplicated AOM. Patients with TM perforations and patients at high risk for treatment failure or those with chronic or recurrent OM are more appropriately treated with a longer course. Shorter courses also are not appropriate for children younger than 2 years old. The antibiotic treatment of AOM in adults is the same as in older children. There is no indication for the use of antihistamines, decongestants, steroids, or tympanostomy tubes for an acute episode of AOM.

AOM can cause substantial pain and should be appropriately addressed. Acetaminophen, ibuprofen, and benzoceantipyre are local anesthetics, may be helpful in some patients with an intact TM. Recurrent AOM occurs primarily in the winter months, often in conjunction with upper respiratory infections. Individual risk factors include children younger than 2 years old, children in day care, and Native American children. These children may benefit from prophylaxis with amoxicillin (20 mg/kg).

After a 10-day treatment with antibiotics, 50% of children may exhibit OME, but 90% of cases resolve within 3 months. However, about 30 to 40% of children have recurrent OME and 5 to 10% of cases last 12 months or longer. The treatment of OME is controversial, but OME may interfere with hearing and subsequent development of speech and language. OME is, by definition, asymptomatic, and the effusion may be sterile. Medical treatment has failed, those who have had OME for 4 to 6 months, and those with a greater than 20-dB hearing loss.

AOM, acute otitis media; TM, tympanic membrane.

Note: Nonsevere illness is mild otalgia and fever <39°C in the past 24 hours. Severe illness is moderate to severe otalgia or fever ≥39°C. A certain diagnosis meets all three criteria: (1) rapid onset, (2) signs of middle ear effusion, and (3) signs and symptoms of middle ear inflammation.

*Type I sensitivity—urticaria or anaphylaxis.*

---

Tonsillectomy is not beneficial, but adenoidectomy may be helpful in older children. Tympanostomy tubes have also been used in recurrent AOM unresponsive to prophylactic antibiotics; complications of AOM, and complications of eustachian tube dysfunction, including TM retraction with hearing loss, ossicular erosions, or retraction pocket formation.64

**Disposition**

Children normally are seen in 10 to 14 days for follow-up. This follow-up appointment may not be necessary in children older than 2 years in whom symptoms have resolved and who have no recurrent risk factors.65 Infants younger than 2 months old with OM should be evaluated with blood, cerebrospinal fluid, and urine cultures.6 Patients with complications need ear, nose, and throat (ENT) referral. Adults who have persistent OME need ENT referral to rule out nasopharyngeal carcinoma.

---

**OTITIS EXTERNA**

**Principles of Disease**

External otitis is an inflammation of the external auditory canal. There is a lifetime incidence of 10%, and it accounts for 7.5 million annual ototopical prescriptions in the United States.67 The external auditory canal is lined with squamous epithelial cells and cerumen glands that provide a protective lipid layer.66 This protective layer may be disrupted by high humidity, increased temperature, maceration of the skin after prolonged exposure to moisture, and local trauma (e.g., cotton swabs or the use of hearing aids), resulting in the introduction of bacteria. Otitis externa is a bacterial disease, most commonly caused by *P. aeruginosa*, *S. aureus*, and other gram-negative organisms often occurring as polymicrobial infection.69

Occurring most often in the summer and in tropical climates, it is also known as swimmer’s ear or tropical ear.

**Clinical Features**

The diagnosis is made clinically. The external auditory canal may be initially pruritic and become erythematous and increasing swollen. Symptoms include otalgia and ear fullness, as well as possible hearing loss or jaw pain. Physical findings include erythema or edema of the canal and reproduction of the discomfort with pulling on the auricle or tragus. There may be associated lymphadenitis, TM erythema, or local cellulitis. The disease may progress to a chronic form with itching, eczema, and flaking of the epithelium, which may be from bacterial, fungal, or dermatologic conditions. In children, it is usually secondary to chronic OM.

**Differential Considerations**

It may be difficult to distinguish otitis externa from OM, particularly in children. The TM may be erythematous in both conditions, and the edema may preclude diagnosis. The discharge may be from otitis externa or a perforated TM, and in equivocal cases it is prudent to treat for both conditions.

Otomycosis or fungal infection can occur as a primary or secondary infection and accounts for 10% of cases of otitis externa.68 Itching is the prominent symptom, often with minimal pain or otorrhea. Aspergillosis is the cause in most cases. Otomycosis appears most often in individuals in tropical climates, in patients with diabetes, in immunocompromised patients, and in patients on immunosuppressive therapy. Treatment involves cleansing and acidifying and antifungal eardrops, such as thimerosal or gentian violet. Specific antifungal agents, such as clotrimazole and itraconazole, also are effective.70
Furunculosis is a small, erythematous, and well-circumscribed infection of the cartilaginous portions of the external canal, usually caused by *S. aureus*. There is usually no drainage, and treatment involves incision, drainage, and an oral antistaphylococcal antibiotic. Cellulitis of the auricle and canal may cause erythema, induration, and other systemic signs. Treatment is with antibiotics directed at the offending organisms.

Herpes zoster oticus, also known as the Ramsay Hunt syndrome, is a viral manifestation of disease affecting the auricle, with resulting facial paralysis that may involve multiple cranial nerves. It initially causes pain, with erythema, swelling, and vesicles developing approximately 3 to 7 days later. These patients need ENT referral. Treatment consists of analgesia, warm compresses, and acyclovir.

**Management**

Historically, combination drugs containing neomycin, polymyxin B, and hydrocortisone (e.g., Cortisporin otic suspension) four times a day have been effective for treatment, although there has been a problem with hypersensitivity to the neomycin component. The new fluoroquinolones are less reactive, have minimal toxicity, and are taken twice a day. The addition of steroid drops may decrease the formation of granulation tissue in the canal. Management may involve cleansing the external canal with a combination of gentle suctioning and irrigation, depending on the amount of obstructing exudate. Cleansing solutions include tap water, sterile saline, 2% acetic acid, and Burow’s solution. In severe infections, a wick of cotton, gauze, or compressed hydroxy cellulose facilitates medication delivery. The wick is placed 10 to 12 mm into the canal, moistened with antibiotic drops, and left in place for 2 to 3 days. Having the patient lie down for 5 minutes after the solution is placed may obviate the need for packing. There is no evidence that systemic antibiotics alone or in combination with topical preparations improve treatment outcome compared with topical antibiotics alone, but systemic medication may be indicated in immunocompromised patients with diabetes or HIV or in infections involving the skin and periauricular areas. Otitis externa can be extremely painful, and severe symptoms may require opiate analgesia. Topical anesthesia such as benzocaine with or without antipyrine may also be used for pain relief, but benzocaine may cause a contact dermatitis that can worsen the disease.

**NECROTIZING (MALIGNANT) EXTERNAL OTITIS**

Previously known as malignant otitis externa because of its associated high mortality rate, necrotizing external otitis is an extremely aggressive form of otitis externa. Patients affected include elderly patients with diabetics, AIDS patients, and, rarely, immunocompromised children. *Pseudomonas* is the predominant pathogen, but *Staphylococcus aureus*, *Streptococcus epidermidis*, *Proteus mirabilis*, *Klebsiella*, *Aspergillus*, and *Salmonella* all have been described. The infection begins in the external canal and progresses through the periauricular tissue and cartilaginous bony junction of the external auditory meatus. It then spreads into the adjacent tissues along clefts in the floor of the meatus known as the fissures of Santorini. It may spread to the base of the skull at the temporal bone, with a resultant skull-base osteomylitis, another term often used to describe this entity. The facial nerve is the first cranial nerve affected, but additional nerves may be involved. The pathogenesis is uncertain but may be related to vascular insufficiency or immune dysfunction.

Patients may present with persistent otorrhea unresponsive to topical medications, otalgia, headache, and periauricular pain and swelling. It should be considered in patients at risk who have a prolonged course of otitis externa. The clinical finding characteristic for the disease is granulation tissue in the floor of the ear canal at the bony cartilaginous junction. Cranial nerve VII is most often involved and manifests in facial paralysis, which occurs when the styломastoid foramen is involved. Further extension can result in involvement of the glossopharyngeal, vagal, spinal accessory, hypoglossal, trigeminal, and abducens nerves. Cranial nerve involvement does not affect mortality rates. Additional complications include meningitis, brain abscess, and thrombosis of the sigmoid sinus.

There is no single diagnostic criterion for necrotizing external otitis. The diagnosis is made from a range of clinical, laboratory, and radiographic findings. Bone scanning (technetium 99 m) is sensitive but is often positive in patients with otitis externa. Gallium scans are more specific, but computed tomography (CT) and magnetic resonance imaging (MRI) are better for detecting infratemporal spread of the disease, bony erosions, and abscess formation. The bioavailability of oral ciprofloxin and its penetration to bone have made it the ideal treatment for necrotizing external otitis, eliminating the need for hospitalization in all but the most recalcitrant cases. Treatment may be required for 6 to 8 weeks. Although extensive surgical treatment was previously required, its use is now limited to diagnostic confirmation or débridement of granulation tissue. Hyperbaric oxygen may be used as an adjunct treatment for advanced disease with significant skull base or intracranial involvement, recurrent cases, and infections secondary to antibiotic treatment.

**MASTOIDITIS**

The incidence of acute and chronic mastoiditis has decreased significantly since the advent of antibiotics, though there is concern about an increase in its frequency. Although it is still associated primarily with OM, many patients have not had an episode of OM. Mastoiditis also has been described as a complication of leukemia, mononucleosis, sarcoma of the temporal bone, and Kawasaki disease.

**Pathophysiology**

Acute mastoiditis is a natural extension of middle ear infections because the mastoid air cells are generally inflamed during an episode of AOM. The aditus ad antrum is a narrow connection between the middle ear and mastoid air cells. If this connection becomes blocked, a closed space is formed, with the potential for abscess development and bone destruction. The infection may spread from the mastoid air cells through venous channels, resulting in inflammation of the overlying peristeum. Progression results in the destruction of the mastoid bone trabeculae and coalescence of the cells, resulting in acute mastoid osteitis or coalescent mastoiditis. The resulting pus may track through many routes: (1) through the aditus ad antrum with resultant spontaneous resolution; (2) lateral to the surface of the mastoid process, resulting in a subperiosteal abscess; (3) anteriorly, forming an abscess below the pinna or behind the sternocleidomastoid muscle of the neck, resulting in an abscess (often called a Bezold abscess); (4) medial to the petrous air cells of the temporal bone, resulting in a rare condition known as *petrosis*; and (5) posterior to the occipital bone, resulting in osteomyelitis of the calvaria or a Citelli abscess.

Chronic mastoiditis is generally a complication of chronic OM. There may be extensive invasion of granulation tissue.
from the middle ear into the mastoid air cells. Another entity, latent, or “masked,” mastoiditis, also has been described. It is indolent in nature, with minimal signs and symptoms, little or no fever, and a history of otalgia. The TM may be intact or perforated. Suspicion should be raised in the presence of intra-cranial complications without an apparent source.87 Patients at risk include newborns and immunosuppressed patients (those who have undergone recent chemotherapy or steroid administration or diabetic or geriatric patients).

**Etiology**

*S. pneumoniae* is the most common organism found in mastoiditis, but other organisms involved do not always mirror those of acute otitis.85 Mixed cultures of aerobes and anaerobes are common. Common aerobes include group A streptococci, *S. aureus*, and *S. epidermidis*. Chronic mastoiditis also often has mixed cultures, with *P. aeruginosa* as the predominant organism.

**Diagnostic Findings**

Clinical findings in acute mastoiditis include fever, headache, and erythema. Pain is universally present.85 Physical findings include postauricular or supra-auricular tenderness, with late edema. The TM is similar to AOM (erythema, bulging, and decreased mobility) but may be normal in 10% of cases.85 Suspicions should be heightened if symptoms of AOM have lasted longer than 2 weeks.87,88 In chronic mastoiditis, symptoms include persistent drainage through the perforated TM, redness, edema, and retroauricular sensitivity.89

**Ancillary Testing**

CT scans can identify the evidence of bony erosions, whereas MRI may be more useful in cases of possible intracranial complications.

**Management**

Antibiotics are the initial treatment of choice, with most cases responding without the need for surgical drainage.84,90,91 If indicated, surgical procedures may range from myringotomy and tympanostomy tube placement (for drainage and identification of the offending organism) to mastoidectomy and drainage for more extensive disease progression.

**SUDDEN HEARING LOSS**

Hearing loss has a multitude of causes (Box 70-1).92-94 Idiopathic sudden sensorineural hearing loss is an otologic emergency.92 It is defined as the idiopathic loss of hearing of 30 dB over at least three test frequencies occurring within 3 days.92 The overall incidence ranges from 5 to 20 per 100,000 people a year.96 Severity ranges from difficulty with conversation to complete hearing loss.

A sudden onset may be from trauma or a vascular complication; gradual hearing loss suggests a tumor.97 A history of trauma, medications, illnesses, physical activity at the time of the event, and unilateral or bilateral involvement all are helpful diagnostic clues. The presence of tinnitus, vertigo, and neurologic symptoms ranging from cranial nerve abnormalities to brainstem or cerebellar dysfunction is suggestive. In conductive hearing losses, such as otosclerosis, individuals hear better in noisy environments.98

Physical examination should include a thorough inspection of the external canal and TM integrity. Weber’s test for hearing and Rinne’s test may help in distinguishing conductive versus sensorineural deficits. A comprehensive neurologic examination including cranial nerves and cerebellar testing may localize brainstem involvement. CT may reveal trauma or tumors, and neurologic and chemical screening should be based on the history and physical findings.94 Oral steroids are the most common treatment though their efficacy is debated.95 Additional treatments have included intratympanic steroids, hyperbaric oxygen, antiviral therapy, vasoactive and hemodilution therapies, dextran, and magnesium, all with mixed results.95-100

**EPISTAXIS**

**Perspective**

**Epidemiology**

Epistaxis is a common otolaryngologic problem, with 15 per 10,000 people requiring physician care annually and 1.6 per 10,000 requiring admission to the hospital.101 Most cases occur
in children younger than age 10 years, and the incidence decreases with age. Some studies have found a bimodal distribution of patients younger than age 25 and those older than 50. Epistaxis is more common in colder seasons and in northern climates because of decreased humidity and subsequent drying of the nasal mucosa. Nasal bleeding is a frightening condition for patients but is seldom life-threatening. A solid understanding of physiology and treatment allows for prompt and efficient management of the disorder.

Anterior epistaxis accounts for 90% of all nosebleeds and usually involves Kiesselbach’s plexus on the anteroinferior nasal septum. Epistaxis is unilateral and can be controlled with anterior packing. Posterior epistaxis accounts for 10% of nosebleeds and usually arises from a posterior branch of the sphenopalatine artery. It cannot be controlled with a well-placed anterior pack. Posterior bleeding is rare in children.

**Principles of Disease**

**Anatomy**

Three arteries with anastomoses between them supply the nasal area. The sphenopalatine artery supplies the turbinates and meatus laterally and the posterior and inferior septum medially. The anterior and posterior ethmoidal arteries from the ophthalmic branch of the internal carotid artery supply the superior mucosa medially and laterally. The superior labial branch of the facial artery provides circulation to the anterior mucosal septum and anterior lateral mucosa (Fig. 70-1).

**Etiology**

There are many reasons for epistaxis, but the most common are upper respiratory infection with concomitant mucosal congestion and vasodilatation and trauma, either accidental or iatrogenic (i.e., nose picking) (Box 70-2).

**Diagnostic Strategies**

Patients initially should have their hemodynamic status evaluated, with resuscitation and laboratory studies performed as needed based on possible causes mentioned in Box 70-2. Patients often are anxious and hypertensive. Elevated blood pressure is usually from stress and anxiety and resolves with treatment. Hypertension has never been shown to cause epistaxis, although it can worsen the bleeding when present. Sedation with benzodiazepines or narcotics may help these patients.

The key to successful management is identifying the site of nasal bleeding and whether it is anterior or posterior. If the nose is actively bleeding, the patient should clear clots by blowing the nose, then apply bilateral pressure on the nasal septum by compressing the cartilaginous part of the nose for 10 to 15 minutes. This simple maneuver also educates the patient on how to self-manage further episodes. It is important to optimize the exam. The patient must have the floor of the nose parallel to the floor. If the head is tilted, only the anterior and upper aspect of the nares can be visualized. The nasal speculum should be opened in an upper-lower direction rather than side to side in the nares. During this time, materials for illumination, suction, visualization, and treatment should be assembled. Discharge without identification and treatment of
the bleeding site often results in recurrences. Anterior clots and obstructions may give the appearance of a posterior epistaxis if the blood runs posteriorly. Persistent bleeding should be controlled with pledgets soaked in cocaine, lidocaine-epinephrine, or phenylephrine (Neo-Synephrine) to promote vasoconstriction and anesthesia.

Management
Anterior Epistaxis
After having identified the site of bleeding in anterior epistaxis, the clinician has several treatment options. Application of silver nitrate chemically cauterizes the area but is directly unsuccessful during active bleeding. With 4 to 5 seconds of application, nitric acid is formed and coagulates tissue. Coagulation should never be maintained longer than 15 seconds because septal damage may occur. The area should be cauterized peripherally to centrally and superiorly to inferiorly to avoid blood, which renders the sticks ineffectual. Bilateral application of silver nitrate to the septum is not advised because it may deprive the septum of a blood supply and theoretically could lead to necrosis. Cautery should not be done in the presence of coagulopathy.

An alternative treatment is the application of topical agents, such as absorbable gelatin sponge (Gelfoam) and absorbable knitted fabric (Surgicel), with light packing. If bleeding persists, anterior tamponade with a commercially available nasal tampon or balloon or a formal anterior nasal pack may be necessary. Occasionally, for uncontrollable bleeding despite the presence of tampon, an second tampon can be inserted adjacent to the first. These work by three mechanisms. Direct pressure is applied, resultant mucosal irritation from the foreign body decreases bleeding, and surrounding clot formation adds further pressure. A recent study of 42 patients found no difference in efficacy or discomfort when the Merocel Sponge was compared with the Rapid Rhino; however, patients experienced greater subjective discomfort from the latter on insertion and removal. When placed, anterior packs should be left in place for about 48 hours. Discomfort caused by anterior packs may require sedatives and opioid pain medication. Bilateral packs usually are required to obtain adequate compression when the patient has significant septal deviation.

It is customary to place patients on antibiotics to prevent sinusitis from obstruction. There is no proof, however, that this is effective. Toxic shock has also been reported in patients with nasal packing and is due to S. aureus. Patients should be instructed on proper nose compression techniques and, after packing is removed, to keep mucosa moist with antibiotic ointment. Patients may be counseled to avoid closed-mouth sneezing, nose picking, coughing, nose blowing, and aspirin.

Posterior Epistaxis
Posterior epistaxis is suggested when posterior bleeding occurs with a properly placed anterior nasal pack. A posterior pack is therefore necessary, with either a commercially available device or basic Foley catheter. A standard Foley catheter may be inserted into the nasopharynx, partially inflated, and then pulled anteriorly, creating pressure posteriorly. A small amount of fluid can be added to the balloon, but caution should be exercised to avoid pressure necrosis. It is recommended that plain water rather than saline be used because saline can crystallize and cause problems with balloon deflation later. Vaseline gauze should be packed around the catheter anteriorly. Commercially available balloons, such as the Nasostat and Epistat, are more comfortable than the posterior pack. The packs are left in for 2 to 5 days to minimize rebleeding and also avoid tissue necrosis associated with prolonged placement. Antibiotics, such as cephalexin and amoxicillin-clavulanate, are traditional medications. If these techniques do not provide successful control, ENT consultation is necessary. Definitive care may require internal maxillary artery ligation or embolization with Gelfoam or posterior endoscopic cautery.

Patients with posterior nasal packs should be admitted to the hospital and may require sedation and supplemental oxygen. The partial pressure of oxygen (PO2) may decrease 10 mm Hg, and partial pressure of carbon dioxide (PCO2) may increase 10 mm Hg after posterior packing. This is thought to be secondary to a postulated nasopulmonary reflex. Dysrhythmias, bradycardia, myocardial infarction, stroke, and aspiration have also been reported after posterior nasal packing.

Newer Agents in Epistaxis
The following three agents have recently become available. To this date, no large studies have examined their efficacy.

QuikClot hemostatic agent is a molecular sieve, sifting molecules by size. When QuikClot comes into contact with blood in and around a wound, it rapidly absorbs the smaller water molecules from the blood. The larger platelet and clotting factor molecules remain in the wound in a highly concentrated form. This promotes extremely rapid natural clotting. The particles provide key surface chemistry, rapidly enhancing the coagulation process. It is available over the counter and is being actively used by police, fire, sports, and military personnel. No clinical trials have been done, but case reports are available. It has been successfully used on a 60-year-old man with uncontrollable bleeding after a punch biopsy of the nasopharynx. "Thermal release due to an exothermic reaction of the product can cause discomfort. Recombinant factor VIIa has been used to treat severe, uncontrolled, life-threatening bleeding. Recently it was used in two patients with Bernard-Soulier syndrome who had life-threatening epistaxis, and it may prove to be useful in uncontrolled epistaxis.

Floseal Hemostatic Matrix is a combination of human thrombin (from pooled plasma), calcium chloride, and a gelatin matrix, which are mixed together and placed at a bleeding site. The manufacturer claims that bleeding, whether it is oozing or pulsatile, ceases within 2 minutes. Bleeding must be active for this method to be effective. Injection into blood vessels or open lacerations is contraindicated. After application, the volume swells approximately 20% and excess volume other than the induced clot should be gently irrigated away. Preparation of the material requires mixing of the materials and then passing the liquid back and forth between two connected syringes 20 times. It may not be used for at least 30 seconds. After mixing it is active for 2 hours.

SIALOLITHIASIS
Stones of the salivary glands occur in 1% of the population. Stones are found most commonly in people between ages 30 and 50 years. Although they are less common in children, a recent study of 210 stones found that 14% occurred in children younger than 18 years. Pediatric stones were more likely to be distal in the duct and smaller. The most common gland affected is the submandibular (submaxillary) gland, accounting for 80 to 95% of cases. They are found in
the sublingual gland about 6% of the time and in the parotid gland in 2%.

The stones occur when calcification occurs around an organic nidus. The patient has pain and swelling of the gland. Differential diagnosis includes infections, inflammation, as well as granulomatous and neoplastic processes. The most common viral pathogen is mumps. Staphylococcus, Streptococcus viridans, S. pneumoniae, and H. influenzae predominate in bacterial infections. Stones may be confirmed by palpation or purulent discharge from the glandular duct with massage. Ultrasonography is rapidly becoming the diagnostic modality of choice as it avoids radiation and may reveal diagnoses other than stones, although CT provides more accurate sizing and location within the duct.\textsuperscript{114}

Treatment consists of antibiotics (covering penicillinase-resistant organisms), moist heat, massage, sialogogues (tart hard candies to promote glandular secretions), and sialolithotomy, if necessary, using probes or endoscopy.\textsuperscript{115} Lithotripsy treatment is also used and works better for parotid rather than submandibular stones. A recent study of 323 submandibular and 132 parotid stones found lithotripsy to be successful in 39.4%, basket retrieval in 74.7%, and intraoral surgical removal in 95.8% of patients attempted.\textsuperscript{116} Procedures are chosen based on stone size and location. For recalcitrant cases, the entire gland may require removal, but this may lead to chronic decreased function and morbidity. Follow-up within 24 hours should be arranged for patients who had stones that were not removed in the ED and 4 to 5 days if the removal is successful in the ED.

\section*{NECK MASSES}

\subsection*{Perspective}

Neck masses are relatively common clinical findings and are usually the result of inflammation but may be an indicator of head and neck malignancy as well. An extensive discussion of head and neck cancer is beyond the scope of this chapter, but some basics are discussed. Children and young adults are more likely to have benign disorders, such as inflammatory or developmental abnormalities, including thyroglossal or branchial cleft cysts. Adult neck masses are more likely to be neoplastic. In general, 80\% of nonthyroid neck masses in adults are neoplastic, of which 80\% are malignant.\textsuperscript{117} In children, however, more than 80\% of neck masses are benign. This is often referred to as the \textit{rule of 80,} or the 80\% rule. Risk factors that may predispose patients to ENT malignancies include alcohol and tobacco use, viruses such as herpesvirus, sunlight exposure, genetics, diet, exposure to dust, and inhalation exposures.\textsuperscript{118}

\subsection*{Principles of Disease}

Identifying the location of the parotid and submandibular glands and thyroid cartilage and thyroid gland can help avoid confusion when evaluating a neck mass. In addition, knowing where the lymph nodes are can help distinguish lymph nodes from other types of masses (Fig. 70-2).

\subsection*{Clinical Features}

Important associated symptoms include dysphagia, odynophagia, otalgia, stridor, speech disorders, and globus phenomena. Dysphagia is difficulty swallowing and may be caused by physical obstruction or neurologic disorders. Odynophagia is pain on swallowing and can be caused by many entities, such as tonsillitis or carcinoma of the pharynx. Otalgia is pain felt in the ear that may be referred from the larynx, pharynx, and cranial nerves V, IX, and X. Referred ear pain is considered an ominous sign in adults and should be presumed to be cancer until proved otherwise.\textsuperscript{119} Unilateral OME in older adults should be considered nasopharyngeal carcinoma until proved otherwise. Stridor, specifically inspiratory stridor, is diagnostic of upper airway obstruction. It localizes a lesion to above or at the level of the larynx and, when present in adults with a neck mass, should increase the possibility of carcinoma. Speech disorders, particularly “hot potato” speech, are suggestive of space-occupying lesions above the oropharynx, a classic example being peritonsillar abscess. The globus symptom is a lump in the throat. It has occurred in almost everyone at one time or another, is localized to the pharynx, and is often a functional complaint.\textsuperscript{119} Hoarseness, the final symptom, is a fairly common complaint, with a myriad of causes, ranging from viral pharyngitis to laryngeal cancer. Also, similar to the term dizziness, hoarseness has many descriptions, including breathiness, muffling, harshness, scratchiness, or unnatural deepening of the voice.\textsuperscript{120} Hoarseness lasting longer than 2 weeks needs investigating.

\subsection*{Physical Examination}

The head and neck examination may identify masses, lesions, mucosal ulcerations or discolorations, and cranial nerve abnormalities. The mass itself should be palpated for location, size, and consistency. Lymph nodes are generally smaller than 1 to 1.5 cm, so any nodes larger than 1.5 cm should be considered abnormal.\textsuperscript{121} Lymph nodes are also mobile, soft, and fleshy. Decreased mobility and firmness are warning signs of malignancy.\textsuperscript{121}
The diagnostic strategy should be tailored to results of the history and physical examination. Hoarseness for longer than 2 weeks should be investigated, generally with fiberoptic examination. Serologic and skin tests may be helpful in certain instances but are best performed by the referring specialist. Chest radiography may identify lung carcinoma as the source of metastasis. Ultrasonography, CT, MRI, and needle biopsy can aid in the diagnosis but usually are not required in the ED.

**Differential Considerations**

Box 70-3 lists common possibilities for the differential diagnosis of neck masses.121-123

**Management and Disposition**

Most masses in children are inflammatory; it is a reasonable strategy, therefore, to start the patient on antibiotics with a 2-week follow-up. If inflammation is considered in adults, a similar strategy can be used.122 Adults generally need ENT referral if the mass does not resolve in 2 weeks, the mass is enlarging, the mass is fixed, cervical lymph nodes are matted, or masses are noted in the parotid or thyroid gland.123

---

**Box 70-3  Differential Diagnosis of Neck Masses**

**Inflammatory**
- Adenitis
  - Bacterial (*Streptococcus, Staphylococcus*)
  - Viral (HIV, EBV, HSV)
  - Fungal (coccidioidomycosis)
  - Parasitic (toxoplasmosis)
  - Cat-scratch disease
  - Tularemia
- Local cutaneous infections
- Sialoadenitis (parotid and submaxillary glands)
- Thyroiditis
- *Mycobacterium avium-intracellulare*
- *Mycobacterium tuberculosis*

**Congenital/Developmental**
- Brachial cleft cyst
- Thyroglossal duct cyst
- Dermoid cyst
- Cystic hydromas
- Torticollis
- Thymic masses
- Teratomas
- Ranula
- Lymphangioma
- Laryngoecele

**Neoplastic**

**Benign**
- Mesenchymal tumors (lipoma, fibroma, neural tumor)
- Salivary gland masses
- Vascular abnormalities (hemangiomas, AVM, lymphangiomas, aneurysm)

**Malignant**
- Primary tumors
- Sarcoma
- Salivary gland tumor
- Thyroid or parathyroid tumors
- Lymphoma

**Metastasis**
- From primary head and neck tumors
- From infraclavicular primary tumors (e.g., lung or esophageal cancer)

AVM, arteriovenous malformation; EBV, Epstein-Barr virus; HIV, human immunodeficiency virus; HSV, herpes simplex virus.

**PERSPECTIVE**

The word *asthma* is derived from the Greek ἀσφαλέσα, signifying panting, and was used initially as a synonym for “breathlessness.” In 1698 Floyd published “A Treatise of the Asthma,” in which he attempted to differentiate asthma more clearly from other pulmonary disorders. Subsequent definitions of asthma highlight concepts of airway hyper-responsiveness, bronchospasm, and reversible airway obstruction but fail to encompass the many facets of this disease.

The National Heart, Lung, and Blood Institute summarizes our current understanding of asthma as “a chronic inflammatory disorder of the airways in which many cells and cellular elements play a role … this inflammation causes recurrent episodes of wheezing, breathlessness, chest tightness, and coughing … episodes are usually associated with widespread but variable airflow obstruction that is often reversible either spontaneously or with treatment. The inflammation also causes an associated increase in the existing bronchial hyperresponsiveness to a variety of stimuli. Reversibility … may be incomplete in some patients.” Asthma is thus a chronic inflammatory disease, and control of symptoms ultimately depends on ameliorating the inflammatory reaction that produces alterations in airway function and structure. Irreversible structural airway changes occurring in response to chronic airway inflammation may influence emergency department (ED) asthma therapies.

**EPIDEMIOLOGY**

*Lifetime asthma* (defined as having ever been diagnosed with asthma by a physician) was reported by 26.7 million persons in the United States from 1980 to 1999,2 31.3 million in 2001,3 32.6 million in 20054 (Fig. 71-1), and 34.1 million in 2006.5 The current prevalence of asthma (defined as individuals who have been diagnosed and currently have asthma) in 2006 was 22.5 million (15.7 million adults and 6.8 million children), and the asthma attack prevalence (the number of persons who had at least one asthma attack in the previous year) was 12.4 million representing 54% of persons currently having asthma.6 Puerto Ricans have a current asthma prevalence 125% higher than non-Hispanic whites and 80% higher than non-Hispanic blacks. Females have a 40% higher prevalence rate than males (this pattern is reversed in children).

Asthma was responsible for more than 1.8 million ED visits in the United States in 20047 (Fig. 71-2) and a similar number in 2005.8 African Americans had an ED visit rate 350% higher than that for whites. Children accounted for over 754,000 ED visits, and the ED visit rate was highest among children age 0 to 4 years. There were 488,594 asthma hospitalizations in 2005,5 Children age 0 to 17 years accounted for 40% of asthma hospitalizations. The asthma hospitalization rate was 240% greater in African Americans than whites and was 35% greater in females than males. Since 1991 hospitalization rates have been highest in children younger than 15 years. Decreases in hospitalization rates have been noted in those older than 45 years from the late 1980s into the early 2000s.7 From 2003 to 2005 there was a 16.2% decrease in hospitalization discharge rates for asthma.5

The estimated financial burden of asthma totaled $19.7 billion in the United States in 2007,5 with approximately 75% attributable to direct costs (hospital inpatient, outpatient, ED and physician services). Prescription drugs represented the highest single direct cost at $6.2 billion. Less than 20% of asthma patients account for 80% of the direct costs.9 Indirect costs attributable to asthma are reflected by decreased productivity. In 2006 asthma accounted for an estimated 10.1 million lost work days in adults and 12.8 million lost school days in children.5 Asthma ranks within the top 10 prevalent conditions causing limitation of activity.

Disturbing increases in mortality related to asthma were reported in the 1980s, with a disproportionate number of deaths occurring in the age range 5 to 34. In the United States, moderation of this trend was noted in the mid-1990s and continued into the present millennium. The United States had one of the lowest rates of asthma mortality in the world in 2004, bettered only by the Netherlands, Finland, and Spain. In the United States in 2003, 4055 deaths from asthma were reported, which decreased to 3816 in 2004.45 The number of asthma deaths has decreased by 18% since 1999. Despite these positive indicators, asthma mortality is 40% higher for females than for males and three times higher for the black than white population.7 New Zealand, Australia, Great Britain, and Canada all reported increases in asthma prevalence,9 hospitalizations, and deaths during the 1980s, with reversal of these trends during the 1990s. Developed nations have higher rates of asthma, which suggests that urbanization and westernization are correlated with increased asthma prevalence. Interestingly, migrants who move from an area of low asthma prevalence to an area of high asthma prevalence assume an increased asthma prevalence, suggesting that environmental factors play a role. Urban areas in the United States (New York City, Los Angeles, and Chicago) have high mortality rates associated with asthma,

Figure 71-2. Number of asthma emergency department visits per 10,000 population: United States, 2004. (From Figure 5 in National Center for Health Statistics: Asthma Prevalence, Health Care Use and Mortality: United States, 2003–2005. http://www.cdc.gov.nchs/products/pubs/pubd/hestats/ashtma03-05/ashtma03-05/fig5.png.)
indicating that poverty and lack of access to medical care may also be major determinants of asthma complications.

Factors that contribute to asthma morbidity and mortality include inadequate patient and physician assessment of an acute episode resulting in undertreatment, overuse of prescribed or over-the-counter medications leading to delays in seeking treatment, failure of physicians to consider previous hospitalizations or life-threatening episodes of asthma, and failure to initiate corticosteroid therapy early in the course of an exacerbation. Socioeconomic factors, environmental influences, and over-reliance on emergency facilities for all asthma care are also contributing factors. Initiatives to educate physicians and patients about asthma pathophysiology, monitoring, and therapy (e.g., National Asthma Education and Prevention Program [NAEPP], Global Initiative for Asthma) may be in part responsible for the moderation of asthma mortality rates.

## PRINCIPLES OF DISEASE

### Pathophysiology

A variety of airway alterations occur in asthma, but airway inflammation is the final common pathway limiting airflow. Bronchoconstriction occurs due to allergic or nonallergic stimuli. Allergens induce bronchoconstriction via release of mediators and metabolic products from inflammatory cells, but nonallergic mechanisms also trigger airway inflammation in exercise, aspirin-induced, and menstrual-related asthma. Compared with healthy individuals, patients with asthma show bronchial hyper-reactivity (hyper-responsiveness) in response to bronchoconstricting stimuli (e.g., methacholine). This hyper-responsiveness of the airways is characteristic of asthma and correlates with the severity of the disease and the need for treatment. Edema, inflammation, mucus production, and airway smooth muscle hypertrophy contribute to bronchoconstriction and hyper-reactivity and further airway obstruction and airflow limitation. Permanent structural airway changes (airway remodeling) may contribute to increased airway obstruction and hyper-responsiveness and decrease the response to therapy. The interaction of these features determines the clinical manifestations and severity of asthma and significantly influences the response to therapy.

Evidence that inflammation is a component of asthma physiology was initially derived from autopsy findings in patients with fatal asthma. The airways revealed infiltration by neutrophils, eosinophils, and mast cells and the presence of subbasement membrane thickening, loss of epithelial cell integrity, goblet cell hyperplasia, and mucous plugs. Subsequent ante-mortem bronchial biopsy findings in patients with even mild degrees of asthma also demonstrate inflammatory changes in the central and peripheral airways that correlate with disease severity. Inflammatory and chemotactic cytokines produced by both resident airway and recruited inflammatory cells are identified in bronchoalveolar lavage washings and pulmonary secretions. Some cytokines initiate inflammatory responses by activating transcription factors that act on genes encoding for proteins that induce and perpetuate inflammation. Cytokines also induce expression of molecules that provide for the adhesion of inflammatory cells to the pulmonary vascular endothelium and allow migration of these cells through the vessel wall into the lamina propria, epithelium, and airway lumen. Others participate in initiation, propagation, and amplification of the local inflammatory response.

Epidemiologic and clinical observations link immunoglobulin E (IgE) and inflammatory reactions in asthma. Antigens (pollen, dander, mites), occupational antigens, and viruses encounter dendritic cells lining the airways. Airway dendritic cells process the antigenic stimulus and migrate to local lymph nodes where antigen presentation to T and B lymphocytes occurs. The cytokines interleukin-4 (IL-4) and IL-13 induce differentiation of activated B lymphocytes that synthesize and release IgE in response to the antigenic stimulus (Fig. 71-3). IgE circulates briefly in the blood before binding to surface receptors on airway mast cells and peripheral blood basophils, lymphocytes, eosinophils, and macrophages. Further interaction of antigen with membrane-bound IgE activates and then releases preformed and generated mediators from these cells.

Mast cells reside in the mucosa and submucosa of the airways. Cross-linking of antigen and surface-bound IgE on the mast cells induces release of preformed mediators such as histamine and initiates the production of prostaglandins (PGs) and leukotrienes (LTs). Antigen-induced IgE cross-linking on mast cells also stimulates synthesis and subsequent release of other cytokines that induce further differentiation and proliferation of inflammatory cells, have chemoattractant properties, and increase adhesion of inflammatory cells to pulmonary vascular endothelial cells. Thus, mast cells may contribute to both the acute and chronic inflammatory reactions occurring in the airways.

Release of preformed histamine from mast cell granules constricts bronchial smooth muscle and causes airway edema, resulting in wheezing and airflow obstruction. This reaction usually resolves within an hour and is referred to as the early asthmatic response. Similar clinical manifestations occur 4 to 6 hours later as a result of cytokines generated and released by mast cells and other local and recruited inflammatory cells. The airflow obstruction and bronchospasm may be prolonged and together are referred to as the late asthmatic response.

Eosinophils are major effector cells in asthma, and their presence is evidence of the allergic nature of this disease. Increased numbers of eosinophils are found in the airways of most but not all asthmatics. They contain granules that release inflammatory mediators including major basic protein, cationic protein, and LTs. Major basic protein causes constriction of airway smooth muscle and desquamation of the airway epithelium. This effect exposes nerve endings, provides submucosal access for inflammatory cells and mediators, and negates epithelial cell regulation of the inflammatory process. Eosinophil cationic protein increases airway mucous produc-
tion and can cause histamine release from mast cells. LTs are potent bronchoconstrictors produced by eosinophils that are more potent than methacholine. LTs also promote the secretion of thick viscid mucus, leading to airway plugging, and enhance airway vascular permeability, leading to airway edema. Eosinophil-produced ILs and granulocyte-macrophage colony-stimulating factor (GM-CSF) stimulate eosinophil proliferation and enhance pulmonary vascular endothelial cell adhesion, which locally amplifies the inflammatory process. Platelet-activating factor, superoxides, and free radicals produced by eosinophils also cause bronchospasm and bronchial tissue destruction. Although eosinophils appear to be pivotal in airway allergic and inflammatory processes, the role of the eosinophil as the central effector cell in asthma is challenged by studies with anti-IL-5 treatment that significantly reduced eosinophil as the central effector cell in asthma is challenged.

Inhibition of COX (cyclooxygenase) decreases production of PGE\(_2\) and tracheobronchial tree as the target organ. Ongoing synthesis and release of cytokines (e.g., IL-1 to IL-18, GM-CSF), PGs, and LTs (Fig. 71-4) are responsible for propagation and intensification of airway inflammation and disruption of the airway epithelial border. The end result of persistent and self-reinforcing inflammation is airway smooth muscle stimulation and structural alterations evidenced by wheezing and airflow obstruction.

Airway epithelial cells are involved in asthma physiology. Inflammatory cells, mediators, and airway viruses can stimulate airway epithelium to produce inflammatory mediators or directly damage the epithelial barrier itself. Abnormal repair processes may further airway obstruction. Nitric oxide (NO) is produced by airway epithelial cells. It is a potent vasodilator and may reflect the presence of inflammation in asthma. Measurements of fractional exhaled nitric oxide (FENO) may prove useful for monitoring the response to asthma therapy. Airway smooth muscle cells may be a contributor to airway dysfunction and obstruction as well as a target by producing proinflammatory mediators and responding to airway inflammation by proliferation, contraction, and hypertrophy.

Airway remodeling is distinctive in chronic asthma and is likely due to the presence of repetitive or chronic airway inflammation. It consists of airway wall thickening, subepithelial fibrosis, mucous gland metaplasia, increases in airway smooth muscle, myofibroblast hyperplasia, and epithelial hypertrophy. Basement membrane thickening may be protective by preventing inflammatory cells and proteins from entering the airway submucosa through a damaged epithelium; simultaneously, this process may be counterproductive by reducing the elasticity of the small airways. Airway remodeling may explain the resistance to therapy observed in patients with prolonged asthma histories and the decline in pulmonary function noted with age. Finally, if asthma is improperly treated, airway remodeling induced by chronic inflammation may lead to the development of chronic irreversible airflow limitation and a shortened life expectancy.

The clinical implications of the immune and inflammatory nature of the early and late asthmatic responses are crucial because therapy may be directed differently toward each phase. Mast cell stabilizers (e.g., beta\(_2\)-agonists) are more effective in the early asthmatic response but are of less use later in the course of an exacerbation. Anti-inflammatory therapy (e.g., corticosteroids, LT antagonists) is more effective in the late asthmatic response. Interference or inhibition of cytokine activities, suppression of chronic inflammation, and modulation of airway remodeling are potential therapeutic targets. Recognition of asthma phenotypes is assuming an increasing importance as different phenotypes (e.g., severe asthma) may have unique patterns of cytokine release and airway remodeling requiring specific therapies that are not useful in milder forms of asthma.

**Miscellaneous Situations**

Aspirin-exacerbated respiratory disease (AERD) was first described more than 100 years ago. The triad of aspirin sensitivity, asthma, and nasal polyps was described in 1922 and popularized in 1968. The prevalence of AERD is 21% in adult and 5% in childhood asthmatics. It occurs more often in women. Nonsteroidal anti-inflammatory drugs (NSAIDs) also precipitate AERD. AERD is a common precipitant of life-threatening asthma—one survey notes that 25% of asthmatics requiring mechanical ventilation have AERD.

Clinically, most patients with AERD develop symptoms in the third decade, frequently after a viral respiratory illness. Over several months, chronic nasal congestion, rhinorrhea, nasal polyps, and anosmia develop often followed by chronic pansinusitis. Bronchial asthma and sensitivity to aspirin (acetylsalicylic acid, ASA) then result. After ingestion of aspirin or a nonsteroidal drug, acute asthma symptoms occur within 3 hours, usually accompanied by profuse rhinorrhea, conjunctival injection, periorbital edema, and occasionally a scarlet flushing of the head and neck. Definitive diagnosis is made by provocation challenges. In most patients 30 to 150 mg of ASA (mean 60 mg) evokes respiratory reactions.

The pathogenesis of AERD is detailed in Figure 71-4. ASA inhibits cyclooxygenase (COX), of which two isoforms are identified. COX-1 produces PGs that are involved in normal physiologic maintenance of renal function, gastric mucosal integrity and hemostasis, and inflammatory states. COX-2 is not expressed in normal physiologic circumstances but pro-

---

PART III
Medicine and Surgery
Section Two

Pulmonary System

Exercise-induced asthma (EIA) has been recognized since the first Olympic games. It occurs in 5 to 20% of the general population, 30 to 70% of elite winter and summer endurance athletes, and in up to 90% of patients with persistent asthma. Atopy is strongly associated with EIA, and up to 40% of patients with allergic rhinitis have EIA. Although EIA was thought to be a distinct clinical manifestation of asthma, most asthmatic patients develop symptoms after a suitable exercise challenge, and EIA may be another reflection of chronic airway inflammation. Clinically, EIA is usually preceded by 3 to 8 minutes of exercise. Peak symptoms usually occur 8 to 15 minutes after exercise is complete and then begin to remit spontaneously; recovery occurs within 60 minutes.

The etiology of EIA remains unclear. In the "osmotic" hypothesis, airway cooling leads to mucosal drying and increased surface osmolality that causes mast cell degranulation and release of inflammatory mediators. The "thermal" hypothesis suggests that airway cooling during exercise followed by rapid rewarming after exercise causes airway vascular congestion and increased permeability, resulting in airway edema and obstruction. Another exercise-specific factor is autonomic deregulation associated with prolonged high-intensity physical training. The predominantly parasympathetic drive of athletes (evidenced by low heart rates) may also increase bronchomotor tone and increase the risk of EIA.

Prophylaxis for EIA with warm-up and a short-acting inhaled beta2-agonist is the therapy of choice. Pretreatment with cromolyn and LT antagonists is also effective. Breathing through the nose may allow warming and humidification of cool dry air during exercise. Long-acting beta2-agonists are usually effective, but tachyphylaxis and loss of efficacy may occur if these agents are used regularly.

Menstruation-associated asthma affects up to 40% of asthmatic women yet receives little emphasis in asthma treatment guidelines. The ratio of female-to-male asthma prevalence increases dramatically after puberty, and health care for asthma increases in the perimenstrual phase. Perimenstrual reductions in peak expiratory flow rates of 35 to 80% are reported. Fluctuations in estrogen and progesterone levels are postulated as causal factors. Estradiol inhibits eosinophil degranulation and suppresses LT activity—estrogen withdrawal in the luteal phase may enhance these actions. In animals, estrogen withdrawal down-regulates beta-receptors and increases cholinergic-induced bronchoconstriction. Progesterone may also have bronchodilator and anti-inflammatory activity, and the rapid decline in progesterone levels prior to menstruation may contribute to increased bronchospasm. Beneficial therapies for perimenstrual asthma include LT antagonists, long-acting beta-agonists, estradiol, progesterone, and gonadotropin-releasing hormone analogues.

Psychological factors may precipitate bronchospasm. Panic disorder and generalized anxiety disorders are more common in asthmatics than the general population. An association between asthma and depression is noted in children. The mechanisms of bronchospasm associated with psychological factors may be related to autonomic nervous system activation or hyperventilation. Compliance may be adversely affected by psychological factors. Relaxation as a therapy for asthma has inconsistent effects; hypnosis may be beneficial. The actual influence of psychological factors in the induction or continuation of an episode of asthma is unknown but probably varies from patient to patient and episode to episode.

Genetics and Asthma

It is likely that asthma is not a single disease but a syndrome with various phenotypes. Clinicians have long recognized various asthma phenotypes (e.g., environmental, occupational, severe asthma), and researchers suspect that different pathophysiologic mechanisms may be responsible for the various manifestations of this disease. Since no biomarker exists to identify the various asthma phenotypes, categorization based on clinical characteristics (e.g., age at onset, treatment resistance), triggers (e.g., environmental/occupational allergens, ASA-induced, exercise-induced), and inflammatory characteristics (e.g., eosinophilic, neutrophilic) is suggested. Understanding that different phenotypes may have different biologic alterations as their basis may enhance our understanding and treatment of these groups. Overlap may occur among the phenotypes, but it is hoped that recognition of various asthma phenotypes can enhance biomarker development, improve genetic assessment, and focus therapies for these distinct groups.

Pathology

Airway secretions evaluated by bronchoalveolar lavage and sputum analysis in patients with mild to moderate asthma reveal increased numbers of mast cells, eosinophils, lymphocytes, and airway epithelial cells. Their presence supports the concept of chronic inflammation in the airways. Endobronchial biopsies may be normal, show only mild histologic changes between attacks, or reveal chronic alterations. Microscopy demonstrates submucosal infiltration with eosinophils and other inflammatory cells along with viscous mucous plugs in the bronchi and bronchioles, increased numbers of goblet cells, and mucous gland hyperplasia. Airway epithelial cells may be damaged or denuded. Immunohistochemistry demonstrates disruption of the tight junctions in the columnar cells, allowing allergens and infectious agents to penetrate into the submucosal area, thereby facilitating toxic, immune, and inflammatory responses. Airway remodeling is evidenced by squamous metaplasia, thickening of the basement membrane due to collagen and fibronectin deposition, and smooth muscle thickening. Neutrophils are the dominant cell type in the airways of some asthmatics, and noneosinophilic asthma may represent a distinct asthma phenotype that is associated with a reduced responsiveness to corticosteroid therapy.

In contrast to patients with mild to moderate asthma, patients with acute severe asthma have inflammatory cells in the airways that consist of more neutrophils than eosinophils and elevated levels of IL-8 responsible for neutrophil activation. Patients with severe asthma and no evidence of inflammation on endobronchial biopsy have been identified, which suggests a pathologic mechanism that may explain resistance to conventional asthma therapies.
Necropsies of patients with status asthmaticus reveal grossly inflated lungs that may fail to collapse on opening of the pleural cavities. Histologic examination reveals luminal plugs consisting of inflammatory cells, desquamated epithelial cells, and mucus. Marked thickening of the airway basement membrane, submucosal inflammatory cells, increased deposition of connective tissue, mucous gland hyperplasia, and hypertrophy of airway smooth muscle are also observed. Bronchiectasis is described in 15 to 20% of asthmatics.\textsuperscript{44} Reports of patients experiencing sudden-onset fatal asthma demonstrate less mucus in the airway lumens, suggesting that terminal events in this group may be dominated by bronchoconstriction without excessive luminal plugging; however, the putative roles of bronchoconstriction versus mucous plugging in sudden-onset fatal asthma are unclear.\textsuperscript{49,50}

\section*{CLINICAL FEATURES}

\subsection*{National and International Guidelines for the Diagnosis and Management of Asthma}

In response to the increasing prevalence, morbidity, and mortality of asthma in the industrialized world, many countries publish guidelines that improve detection and treatment. Some of these, including the U.S. National Asthma Education and Prevention Program (National Institutes of Health) Expert Panel Report 3 (EPR-3), devote specific portions to the management of acute exacerbations of asthma.\textsuperscript{1,31} The EPR-3 is further condensed as a practical summary for emergency physicians\textsuperscript{52} but has not yet been independently critically analyzed by our specialty, as with the previous EPR-2.\textsuperscript{53} The EPR-3 recommendations are graded from levels A through D based on the strength of the scientific evidence. These national asthma guidelines provide a common set of recommendations for management.\textsuperscript{54} The American Heart Association has guidelines regarding the management of near-fatal asthma, filling a void in the EPR-3 regarding the management of the sickest acute asthmatics.\textsuperscript{55}

\subsection*{Symptoms}

Most patients with acute asthma have a constellation of symptoms consisting of cough, dyspnea, and wheezing. Cough often begins early in the attack, may be the sole manifestation of the disease in cough-variant asthma and elder patients, can be associated with sputum production, and is probably the result of subepithelial vagal stimulation. Nocturnal worsening is common, with most patients reporting cough or wheeze at least once per week. Nighttime mortality is higher than in the general population. Although increased airway resistance, diminished flow rates, and increased bronchial hyperactivity are contributing factors, asthmatic patients who present nocturnally to the ED have disease severity similar to that of other asthmatics. Up to 40% of asthmatic women suffer from premenstrual worsening of symptoms, which peak 2 to 3 days before menses and are associated with more severe disease.\textsuperscript{56} ED visits increase during the prevulatory and perimenstrual intervals.

There are interindividual differences in the dyspnea perceived by asthmatic subjects for the same level of airway narrowing. This difference results in poor correlation of symptoms with airway obstruction as determined by pulmonary function testing (PFT), both chronically and on presentation to the ED. Patients with a blunted perception of dyspnea (the “poor perceivers”) have more ED visits, hospitalizations, and near-fatal and fatal asthma attacks.\textsuperscript{57}

Wheezing that develops reflects air movement velocity and turbulence, and its intensity varies according to the radius of the bronchi. With severe airway obstruction, it decreases or vanishes because air movement velocity is insufficient to produce sound.

Many asthmatics report symptoms of gastroesophageal reflux that may cause airway narrowing through a vagally mediated pathway or microaspiration. Proton pump inhibitor therapy decreases asthma symptoms in these patients. Approximately 80% of patients with asthma have symptoms of rhinitis. Approximately 5 to 15% of patients with perennial rhinitis have asthma, and control of sinonasal inflammation can lead to asthma improvement. Overweight (BMI = 25 kg/m²) asthmatics have higher admission rates and risk of complications, possibly secondary to a difference in the perception of dyspnea or in response to asthma controller agents.\textsuperscript{58,59}

Lastly, as asthma can appear at any age, including the ninth decade, wheezing and dyspnea may be misattributed by both patients and physicians to heart failure, bronchitis, chronic obstructive pulmonary disease (COPD), occupational lung disease, or poor exercise capacity.

\subsection*{Historical Components}

Slow-onset asthma with progressive deterioration over a period of at least 6 hours (usually days) occurs in over 80% of cases. This type has a female predominance, is triggered by upper respiratory tract infections, and has an airflow inflammation mechanism that results in a slower response to treatment. Sudden-onset asthma with rapid deterioration in under 6 hours occurs in less than 20%. This type has a male predominance, is triggered by respiratory allergens, exercise and psychosocial stress, and has a bronchospastic etiology resulting in more severe airway obstruction with a faster response to therapy.\textsuperscript{60}

Risk factors for death from asthma are important to determine and are listed in Box 71-1.\textsuperscript{1,61,62} In urban areas, heroin and cocaine abuse are commonly associated with the need for intubation in the ED.\textsuperscript{63}

The brief history pertinent to the current exacerbation should include onset and possible triggers, severity of symptoms especially as compared with previous exacerbations, and other comorbidities (especially those that may be worsened by systemic corticosteroids such as diabetes, peptic ulcer, hypertension, and psychosis). In addition, all current asthma medications should be noted, including times and amounts recently used, and any potential asthma exacerbators such as aspirin or NSAIDs, beta-blockers (including topical agents used for glaucoma), and angiotensin-converting enzyme inhibitors.

**Physical Assessment**

Those who suffer from mild acute asthma usually speak in sentences, moderate in phrases, and severe in words. Although alterations in mentation or consciousness indicate severe asthma, restlessness and agitation do not reliably indicate hypoxia or hypercapnia. Patients who sit upright have severe airway obstruction; cyanosis is uncommon because of the left shift of the oxyhemoglobin dissociation curve produced by respiratory alkalosis. Diaphoresis can be seen secondary to the work of breathing, but if profound it is usually accompanied by a decreasing level of agitation and interaction with caregivers and may be preterminal. Tachypnea and tachycardia greater than 120 beats/min are associated with severe obstruction, but a lower rate does not rule out severe asthma. The respiratory rate correlates poorly with PFT and indicates severe obstruction only if it is more than 40 breaths/min.

A pulsus paradoxus or inspiratory fall in systolic blood pressure greater than 10 mm Hg usually signifies severe disease, but its absence does not exclude it, and it rarely is contributory when taken in the context of the patient’s overall evaluation. Its use predated common availability of bedside spirometry, which is a more accurate and reliable test. When pulsus paradoxus is present, it may disappear with minimal improvement in airflow through larger airways. Similarly, use of accessory muscles of respiration (sternocleidomastoid and scalenus muscles) is not prognostic.

Wheezing does not designate the presence, severity, or duration of asthma. It correlates poorly with the degree of functional derangement and may be absent when maximal effort produces minimal airflow. Physical examination may help to identify such complications of asthma as pneumonia, pneumothorax, or pneumomediastinum that may arise atypically as subcutaneous emphysema or simulate upper airway obstruction.

**DIAGNOSTIC STRATEGIES**

**Pulmonary Function Studies**

Because the severity of airflow obstruction cannot be accurately assessed from symptoms and physical exam alone, physicians tend to underestimate the degree of airway obstruction in acute asthma, particularly on initial assessment. Therefore, routine PFTs should be part of ED assessment and monitoring. The forced expiratory volume in 1 second from maximal inspiration (FEV₁) or the peak expiratory flow rate (PEFR) in liters per second starting with fully inflated lungs and sustained for at least 10 msec may be used. Both measurements require the patient’s cooperation for maximal effort and are effort-dependent. Whenever possible, the best of three consecutive values should be recorded. Any patient not able to perform a pulmonary function study should be considered to have severe airway obstruction.

Most asthmatic assessments in the ED use single-patient-use portable peak flow meters because PEFR is easier to measure. There is wide limit of agreement between different devices, so a single device should be used to assess then reassess an individual patient, and different portable meters should not be used interchangeably. Lastly, although generally similar, the FEV₁ and PEFR measurements do not appear to be interchangeable in assessing acute airway obstruction, which is not addressed in all management guidelines.

Although absolute PFT measurements can be used, percentage of predicted performance (% predicted) values are preferable because they account for the individual’s age (now to age 85), sex, and height. Ideally, the percentage of the patient’s personal best effort individualizes the assessment and treatment.

**Arterial Blood Gas Analysis**

Using pulse oximetry, changes in equilibration of oxygen saturation with supplemental oxygen occur in 3 to 4 minutes during an acute asthma attack. With initial onset of an asthma attack, stimulated hyperventilation leads to a modest fall in the partial pressure of carbon dioxide in arterial blood (PaCO₂). As airway obstruction increases, the PaCO₂ normalizes (PFT 15–25% predicted) and then increases (PFT < 15% predicted) with worsening hypoxemia. Because neither pretreatment nor post-treatment arterial blood gases (ABGs) correlate with PFTs or predict clinical outcome, ABG determination is rarely clinically useful in acute asthma exacerbations unless oxygen saturation cannot be obtained reliably using pulse oximetry. ABG determination is of no value in determining the need for tracheal intubation.

ABG sampling, if used, should be limited to a subset of patients with predicted PFTs of less than 30%, whose clinical course is perplexing and for whom capnography is not available. Occasionally, despite PFTs improving with bronchodilator therapy, some patients have a transient fall in the PaO₂ secondary to pulmonary vasodilatation and worsening ventilation-perfusion mismatch. The assessment of ventilation may be simplified since there is a high concordance between end-tidal partial pressure of CO₂ (PetCO₂) measured by capnography and the PaCO₂ obtained with ABG measurements.

**Other Blood Testing**

Leukocytosis is common in patients with acute asthma exacerbation, but is not of discriminatory value in determining whether patients with fever or purulent sputum have acute superimposed pulmonary infection. Of note, corticosteroid and epinephrine therapy demarginate polymorphonuclear leukocytes after 1 to 2 hours, and patients on chronic steroid therapy may have normal or significantly elevated WBC counts.

Serum electrolytes are not primarily altered unless the patient is on corticosteroids or diuretics or has cardiovascular disease and is receiving aggressive beta₂-agonist therapy. Frequent albuterol treatments can cause transient hypokalemia, hypomagnesemia, and hypophosphatemia, but this is rarely of clinical significance. The few remaining patients who are receiving chronic theophylline therapy should always have serum levels measured to assess for possible toxicity and for appropriate further dosing if deemed necessary.

In the older asthmatic with cardiovascular comorbidities who presents with wheezing, measure the B-type natriuretic peptide (BNP) level to determine the contribution of unrecognized congestive heart failure to the clinical picture.

Radiology Studies

A chest radiograph is of little value in most acute asthma exacerbations, and its use should be restricted to patients thought to have a complicating cardiopulmonary process such as pneumonia, pneumothorax, pneumomediastinum, or congestive heart failure. Also, patients who do not respond to optimal therapy and require hospital admission have a higher likelihood of radiographically identifiable, unsuspected, clinically significant pulmonary complications of asthma (15% of cases).71

Electrocardiogram and Cardiac Monitoring

The electrocardiogram (ECG) need not be routinely obtained, except in patients older than 40, those with a separate complaint (e.g., chest pain) that would prompt an ECG, or those with a history of significant cardiovascular disease, in whom the asthma attack may be a form of physiologic stress test. In patients with severe asthma, the ECG may show a right ventricular strain pattern that reverses with improvement in airflow. Older patients, especially those with coexistent heart disease or with severe exacerbation, may require continuous cardiac monitoring to detect dysrhythmias. All patients with severe hypoxemia, and those for whom intubation is contemplated, should have continuous cardiac monitoring.

Future Monitoring Strategies

Noninvasive monitoring of bronchial inflammation may customize the ED assessment of acute asthma. This may include measurement of biologic biomarkers such as cytokine profiles in the blood, evaluation of LTE4 in the urine, and the monitoring of exhaled pentane, hydrogen peroxide, nitric oxide, or carbon monoxide levels. Of these measurements, exhaled nitric oxide shows the most promise in chronic asthma management but provides little aid in assessing the severity of acute exacerbations.72

Assessment Summary

The severity of airflow obstruction cannot be accurately judged by patients’ symptoms, physical examination, and laboratory tests. Serial measurements of airflow obstruction (FEV1 or PEFR) are key components of disease assessment and response to therapy. A more detailed analysis between commonly measured variables and patients with severe asthma (FEV1 < 1 L) is shown in Table 71-1.

Differential Considerations

See Box 71-2.

Management of Acute Exacerbations

Home and First-Responder Strategies

Patients should be educated to monitor their symptoms, signs, and PEFR to recognize early deterioration and should be provided with a written action plan in the event of an exacerbation. Early therapy can prevent progression to severe attacks. Home management includes increased use of inhaled beta-agonists, early administration of systemic corticosteroids (not simply doubling the dose of current inhaled corticosteroids), and specific instructions on when and how to seek emergency care.4 Ideally, emergency medical service providers should

provide albuterol inhalation therapy by protocol during transport to the hospital. Basic emergency medical technicians can be authorized to administer the patient’s own inhaler.24,75

Management of Acute Asthma in the Emergency Department

The goal in the ED is to reverse the acute airflow obstruction safely, and the rapidity of this reversal is directly predictive of the outcome of the attack.76 Effective bronchodilation often results in a decreased need for hospitalization with significant cost savings.77 As outlined in Table 71-2, the severity of attack as measured by PFTs determines the aggressiveness of the therapy.

Oxygen Administration

All patients should receive supplemental oxygen to maintain an arterial oxygen saturation above 90% (>95% in pregnant women and those with coexistent heart disease) rather than using predetermined concentrations or flow rates. Serial oxygen saturation monitoring is essential during the acute phase. Humidification of the inspired air-oxygen mixture is not essential, although studies suggest that active airway rehydration should be revisited.78

Adrenergic Medication

Controversies in Use. Epidemiologic studies report an association between death and near death from asthma and the use of inhaled beta2-agonists, with use of more than one canister per month increasing this risk that doubles for each additional monthly canister used.79 This relationship does not imply causality but may be a marker for more severe disease, particularly if anti-inflammatory treatment is underused. Guidelines for chronic use of inhaled beta2-agonists, however, recommend limited daily use in a rescue-only mode.1

One form of albuterol is a racemic mixture of equal amounts of R and S isomers. Data from animal and human studies suggest that the S isomer, which contributes no bronchodilator activity, is proinflammatory, spasmogenic, and induces bronchial hyper-reactivity. This possibly explains the adverse effects of increased morbidity and mortality rates associated with regular or excessive use of this drug.80

Some investigations of the beta-adrenergic receptor polymorphisms show differential responsiveness to inhaled albuterol, a possible explanation for the widely varying responses seen clinically when treating patients with acute disease.81

Short-Acting Inhaled Beta2-Agonist Choice and Dosing Schedule. Racemic albuterol has been the main beta2-agonist used in the ED for over 30 years. It is more beta2-selective, longer acting, and has fewer side effects than other previously available drugs such as metaproterenol or isoetharine.

Levalbuterol, the R isomer of racemic albuterol, is commercially available as a preservative-free nebulizer solution (unit doses of 0.31, 0.63, or 1.25 mg) for prevention and treatment of bronchospasm. In chronic asthma, levalbuterol provides a better therapeutic index than the standard dose of racemic albuterol, further fueling the debate on the potential adverse effects of the S isomer of beta-agonists.82 Clinical studies in acute disease report that levalbuterol on a milligram for milligram basis is a better bronchodilator than similar amounts of R-albuterol delivered with the S isomer in the racemic mixture.83,85 This reinforces the notion that the S isomer has a negative rather than neutral effect.

The amount and frequency of delivery of levalbuterol and racemic albuterol depend on the initial severity and response to therapy, as shown in Table 71-2 and Table 71-3. Patients with more severe obstruction with a poor response to initial therapy should receive higher dosing schedules and possible continuous administration.86 When patients are stable but require nonintensive care unit (ICU) admission, it may be possible to dose nebulized levalbuterol at 1.25 mg every 8

hours as opposed to racemic albuterol at 2.5 mg every 4 to 6 hours.

**Nebulizer versus Metered-Dose Inhaler and Valved Holding Chamber.** A metered-dose inhaler (MDI) plus a valved holding chamber, used often and frequently (see Table 71-2), provides similar bronchodilation and side effects, even in severe asthma, when compared with wet nebulization. This therapy requires more supervision because some patients have difficulty firing the canister before inhalation, breathing slowly, and holding their breath for 5 seconds, which may explain the infrequent use of canisters in the ED. Wet nebulization by mouthpiece or mask requires no coordination and minimal cooperation and is less expensive.

**Intravenous Use of Adrenergic Agonists.** Most international asthma guidelines, with the exception of those in the United States, recommend the use of intravenous (IV) beta-agonists for severe nonresponsive acute asthma. IV albuterol (not available in the United States) is given as a loading dose of 4 µg/kg for 2 to 5 minutes followed by an infusion of 0.1 to 0.2 µg/kg/min, with close cardiopulmonary monitoring.

Some reviews conclude that evidence is lacking to support the use of IV beta-agonists in ED patients with severe acute asthma because the potential risks are warranted only when inhaled therapy is not feasible. Epinephrine is used cautiously in patients older than 40 years of age or those with suspected cardiovascular disease, because it might provoke myocardial ischemia. Epinephrine IV titrated to effect (average 1.5 µg/min with a range of 0.5–3.3 µg/min) is associated with a low rate of major (3.6% of cases) and moderate or minor adverse events.

**Subcutaneous Adrenergic Agents.** Subcutaneous use of adrenergic agents does not have an advantage over aerosol delivery. They may be considered in patients who cannot adequately inhale albuterol or who experience severe bronchospasm.

Epinephrine has been a mainstay for almost 100 years. It has both alpha and beta effects and can produce tachycardia, hypertension, dysrhythmias, and vasoconstriction, especially in older asthmatics with heart disease. Given the potential for increased side effects, it can be given subcutaneously (1:1000 solution 0.2 to 0.5 mL every 20 to 30 minutes as needed for three doses).

Terbutaline is a longer-acting beta-agonist with bronchodilating properties equivalent to those of epinephrine in acute asthma. It can cause skeletal muscle tremor and tachycardia.

A 0.25-mg dose can be given subcutaneously every 20 minutes for three doses.

**Long-Acting Beta-2-Agonists and Acute Disease.** Salmeterol is a long-acting (12 hours) beta-2-agonist that is an effective additional medication for management of daytime and nocturnal symptoms that are not adequately controlled by regular and adequate doses of effective controller medications such as inhaled steroids. It has an onset of action of 20 minutes and thus is not indicated for the treatment of acute attacks. Regular use of this drug without concomitant use of inhaled steroids results in greater asthma-related deaths, resulting in a black box warning on the package insert. The controversies regarding regular use of short-acting beta-agonists extend to the long-acting classes.

Racemic formoterol dry powder and solution and single-isomer arformoterol are other long-acting beta-2-agonists that have an onset of action within minutes (similar to albuterol) and maximal effect within 2 hours. These drugs could evolve as acute rescue medications with extended length of action (12 hours) and similar safety profiles.

Patients receiving chronic long-acting beta-agonists but with acute asthma attacks are treated in the same way as all other asthmatics.

**Corticosteroids**

Corticosteroids have been used to treat asthma for approximately 50 years, and there is general agreement about their effectiveness. Their main action in the airways is inhibition of recruitment of inflammatory cells and inhibition of release of proinflammatory mediators and cytokines from activated inflammatory and epithelial cells. Corticosteroids activate cytoplasmic glucocorticoid receptors to regulate directly or indirectly the transcription of certain target genes resulting in the synthesis of new proteins.

Despite the long history of corticosteroid use, the resolution of fundamental acute care issues remains uncertain. These include the types and quantities required to induce a rapid remission, the time needed for drug action, the route of administration, the existence of dose-response effects, and the determination of which patient populations respond to this therapy.

**Systemic Corticosteroids in the Emergency Department.** These medications should be given promptly to all patients with moderate to severe attacks or those experiencing an incomplete response to initial beta-agonist therapy. In addition, early systemic corticosteroids should be considered for patients who are taking oral or inhaled corticosteroids, have relapsed after a recent exacerbation, or have prolonged symptoms. Steroid effects begin within hours (not minutes) in acute asthma and increase to peak over 24 hours. Use of systemic steroids speeds the resolution of airflow obstruction, reduces the rate of relapse and may decrease admissions in severe, but not in mild to moderate attacks. The PEFR may improve within 2 hours of steroid therapy in those not responding to initial albuterol inhalation.

Many studies have clearly demonstrated that oral corticosteroids are as beneficial as IV corticosteroids in the ED management of an acute asthma exacerbation. Initial oral dosing is usually 60 mg of prednisone. If IV methylprednisolone is used, the dose is 40 to 80 mg/day in one or two divided doses until the patient can be switched to oral therapy, or PEFR reaches 70% of predicted or personal best.

Continuing therapy with oral prednisone or prednisolone is given in an adult dose of 40 to 80 mg/day, usually as a single dose. No study demonstrates the superiority of IV corticosteroids over oral preparations. Oral steroid therapy is preferred unless the patient is very ill, is unable to swallow or is vomit-
Side effects of short-term (hours or days) steroid use include reversible increases in glucose (important in diabetes) and decreases in potassium, fluid retention with weight gain, mood alterations including rare psychosis, hypertension, peptic ulcers, aseptic necrosis of the femur, and rare allergic reactions.

Inhaled Corticosteroids in the Emergency Department. Using inhaled corticosteroids (ICS), either alone or in addition to systemic steroids, to treat acute asthma has the potential benefits of reducing systemic side effects, directly delivering medication to the airway, and reducing airway reactivity and edema more effectively. Patients treated with ICS are less likely to be admitted whether they received systemic steroids or not, and no increased cough or bronchospasm is seen with their use. The optimal agents, delivery system, and doses of ICS given over hours may be necessary for them to be effective. Patients treated with these agents have early improvement in outcomes (<3 hours) because of their topical effects. High doses of ICS given over hours may be necessary for them to be effective. The optimal agents, delivery system, and dosing regimens, however, need to be determined, as well as whether these agents can replace systemic steroids in any patients.

Corticosteroids and Discharged Patients. Discharged patients who have received systemic corticosteroids in the ED should continue oral outpatient “burst” therapy to control disease and prevent relapse. Any need for additional steroids should be determined at the patient’s follow-up outpatient visit. An acceptable regimen is 40 to 60 mg of prednisone (or equivalent) in single daily dose for a total of 5 to 10 days. Dose tapering to prevent asthma rebound or out of concern for adrenal suppression is unnecessary unless the patient was already receiving systemic steroids or a prolonged course of therapy (more than 2 weeks) is deemed necessary. An alternative approach, if compliance may be an issue, is to give an equally efficacious single depot dose of triamcinolone diacetate (40 mg) or methylprednisolone (160 mg) before ED discharge.

Patients who present to the ED for acute exacerbations of asthma may be taking insufficient amounts of chronic controller medications based on their symptoms and excessive use of beta2-agonists. If the patient is not taking oral or ICS, the addition of inhaled high-dose budesonide (400 µg, two puffs twice per day) to the patient’s regular asthma medications on ED discharge improves symptoms and decreases relapse by approximately 50% in the ensuing 3 weeks. Thus patients with a history compatible with persistent asthma but not taking any ICS should be given a prescription (1–2 month supply). Suggested regimens include budesonide dry powder inhaler (DPI) 1200 µg, flunisolide MDI 2000 µg, fluticasone DPI 500 µg, mometasone DPI 400 µg, or triamcinolone MDI 1500 µg in daily divided doses (twice per day) in addition to their prednisone. Patients already taking ICS therapy should continue it. Patients should use a spacer device if using an MDI and be reminded to rinse their mouths after steroid inhalation to decrease the side effects of dysphonia and oral or esophageal candidiasis.

Corticosteroid-Resistant Asthma. Chronic asthma is considered a steroid-responsive disease. A small proportion of asthmatics do not respond to even high doses of oral and inhaled glucocorticoids, which complicates management. The mechanism of this steroid resistance may be related to abnormalities in the glucocorticoid receptor number or binding properties. These patients are usually receiving alternative therapies such as cyclosporine, methylxtrate, troleandomycin, hydroxycholoroquine, azathioprine, gold, IV immune globulin, or (if with severe allergic asthma) maintenance anti-IgE recombinant humanized monoclonal antibody (omalizumab).

Anticholinergic Agents

The atropine-containing botanicals Datura stramonium (stinkweed or thorn apple) and Atropa belladonna (deadly nightshade) were smoked centuries ago in India for treatment of asthma. In the 19th century smoking leaves of the Datura species was common in England, and by the middle of the last century Salter’s treatise on asthma listed D. stramonium as one of asthma’s truly effective remedies. Atropine-containing cigarettes or powders smoked in pipes were available into the 20th century.

The anticholinergic drugs available for inhalation therapy include atropine sulfate, atropine methylbromide, glycopyrrolate, and ipratropium bromide. They are all bronchodilators that override the smooth muscle constrictor and secretory consequences of the parasympathetic nervous system, blocking reflex bronchoconstriction and reversing acute airway obstruction. Since atropine use is associated with side effects and glycopyrrolate is not well studied, the discussion is limited to ipratropium bromide (Atrovent), a quaternary derivative of atropine that is poorly absorbed from the mucosal surfaces of the lung, resulting in decreased side effects.

The maximum effect with inhaled ipratropium is in 30 to 120 minutes, with the effect lasting for up to 6 hours. Its bronchodilating potency is lower and onset of action slower than those of the beta2-agonists; hence, it should not be used alone in patients with acute asthma. Reviews of trials assessing the role of this drug in combination therapy with beta2-agonists for acute disease found that ipratropium provides a modest improvement in PFTs and a reduction in hospitalizations. This benefit is higher in patients with more severe disease.

There is wide interpatient variability in response to anticholinergic therapy, implying that cholinergic mechanisms play a varied and unpredictable role in acute attacks.

Treatment recommendations (see Table 71-2) include adding ipratropium (0.5 mg) with the first three albuterol treatments in severe acute asthma (<40% predicted). The equivalent MDI dose is approximately eight puffs (18 µg/puff) every 20 minutes three times. Data suggest that less ipratropium might be needed in patients treated with levalbuterol nebulizations. Ipratropium can be given to anyone, both acutely and at discharge, who has documented improvement with its past use. There is evidence that ipratropium may be more effective in patients older than 40 years, should be used in reversing bronchospasm secondary to beta-blocking agents, and might help those in whom psychological factors contribute to their disease.

Magnesium Sulfate

Magnesium relaxes bronchial smooth muscle in vitro and dilates asthmatic airways in vitro. Mechanisms for this direct relaxing effect on bronchial smooth muscle include calcium channel-blocking properties, inhibition of cholinergic neuro-muscular transmission, stabilization of mast cells and T lymphocytes, and stimulation of nitric oxide and prostacyclin. Intracellular magnesium levels are lower in acute asthma, and the level correlates with airway reactivity in chronic disease.

There is some evidence that IV magnesium therapy for severe attacks might obviate the need for intubation. Clinical trials and meta-analyses show that magnesium adjunctive administration in severe asthma attacks (FEV1 < 25% predicted) improves airflow obstruction and decreases the need for hospital admission. The optimal dose and rates of infusion are unclear, but it is reasonable to administer 2 to 3 g of IV magnesium sulfate over 20 minutes or at rates of up to
1 g/min to patients with severe refractory asthma while continuing aggressive inhalation therapy.

Uncommon and manageable side effects of magnesium infusion are dose-related and include warmth, flushing, sweating, nausea and emesis, muscle weakness and loss of deep tendon reflexes, hypotension, and respiratory depression. Inhalation magnesium in acute asthma may also have a role as an isotonic vehicle for nebulized bronchodilator therapy in improving the PFT response or even be nebulized alone for bronchodilation. The doses needed, delivery systems required, and timing of magnesium nebulizations remain under investigation.

Methylxanthines

The naturally occurring methylxanthines caffeine and theobromine (in coffee, tea, and cacao) have been used by asthmatics for hundreds of years to treat wheezing. Theophylline is the main oral methylxanthine used to treat asthma; aminophylline (80% theophylline by weight) is used intravenously. The mechanism for theophylline’s bronchodilatory effects is unclear, and current therapeutic approaches capitalize on its nonspecific arousal properties in COPD (increased ventilatory drive) rather than bronchodilation. Theophylline also enhances diuresis, cardiac output, mucociliary clearance, ventilatory drive, and contractility of the diaphragm while inhibiting the release of inflammatory mediators and suppressing microvascular permeability. A number of studies of chronic asthma demonstrate additional potential anti-inflammatory and immunomodulatory activity, and may explain the usefulness of theophylline in nocturnal asthma and moderate asthma managed with ICS. A small subset of ambulatory asthma patients may benefit from the chronic administration of theophylline. Theophylline has a narrow therapeutic window. Significant side effects can affect the cardiovascular, gastrointestinal, CNS, and metabolic systems.

It is important to recognize that the NAEP EPR-3 does not recommend the use of methylxanthines for treatment of acute disease in the ED or in the hospital because of their lack of demonstrated efficacy and increases in adverse events.

Leukotriene Modifiers

The cysteinyl leukotrienes (LTC4, LTD4, and LTE4) are highly potent mediators of inflammation thought to play a large role in the pathogenesis of asthma. Zafirlukast (20 mg twice a day) and montelukast (10 mg daily) are rapid-acting, safe, asthma controller drugs, taken orally, that are potent and highly selective antagonists of type 1 cysteinyl LT receptors.

Asthmatics generally produce elevated levels of LTs, and in acute attacks the levels in the urine can be markedly increased. The addition of either 7 or 14 mg of IV montelukast (not available in the United States) to standard therapy for acute asthma causes a 15% non-beta2-mediated increase in FEV1 over placebo with no increase in side effects. Oral zafirlukast, when given as adjunctive therapy (20 or 160 mg) for acute asthma in the ED, improved PFTs and dyspnea but did not decrease admissions to the hospital. The acute non-beta2-mediated bronchodilating effects of these relatively safe medications could be very useful in managing acute disease.

Other or Future Therapies

In patients without signs of dehydration or hypovolemia, there is no evidence that vigorous administration of fluids aids in clearing airway secretions. Mucolytics may worsen cough or airflow obstruction, and chest physical therapy is not beneficial. Sedatives are contraindicated in acute disease because of their respiratory depressant effect.

Bacterial, chlamydial, and mycoplasmal respiratory tract infections infrequently contribute to acute asthma. The decision to administer antibiotics should generally be reserved for patients with fever, purulent sputum, pneumonia, or evidence of bacterial sinusitis.

Future asthma therapies may include the second-generation antihistamines, even though earlier compounds were considered contraindicated in the disease. Neurokinin antagonists, inhaled loop diuretics (furosemide in acute attacks), and lidocaine may inhibit neurogenic inflammation, and heparin may have a role in the inhibition of mast cell products. Infused BNP can cause significant bronchodilation in patients with asthma. Lastly, specific cytokine antagonists, agonists, inhibitors of T-cell function, selective inducible nitric oxide synthetase inhibitors, and possibly gene-directed therapies may become novel treatments.

Pregnancy and Acute Asthma

The maternal and fetal risks of uncontrolled asthma are high, and acute disease should be maximally treated with the prevention of maternal and fetal hypoxia as the principal goal. Maternal asthma is not associated with preterm birth or birth defects. Many complications of pregnancy (e.g., hypertensive disorders, antepartum hemorrhage, low birth weight, need for cesarean section), however, are reported. Asthmatic African American women are more likely to require an ED visit, inpatient hospitalization, or a course of corticosteroids due to asthma during pregnancy. Pregnant asthmatics receive corticosteroid therapy in the ED less often than nonpregnant women, resulting in continued exacerbation at 2-week follow-up after discharge. Inhaled beta-agonists and corticosteroids should be continued during pregnancy. Although conflicting data regarding the use of systemic corticosteroids during pregnancy exists, their use is suggested in severe uncontrolled exacerbations as the risk to mother and fetus far outweighs the potential complications. Continuous electronic fetal monitoring should be considered at delivery. Recommendations for managing asthma during lactation are the same as those for managing the disease during pregnancy.

Severe, Near-Fatal, and Fatal Asthma

The American Thoracic Society has developed a consensus definition for identifying severe and refractory asthma that is unresponsive to conventional therapies (Fig. 71-5). Termed severe asthma, patients with these symptoms represent only about 10% of all asthmatics yet account for 30% of asthma-related health care costs and have the highest morbidity and mortality rates associated with this disease. To satisfy the definition of severe asthma, medical conditions that mimic asthma must be excluded, exacerbating factors (e.g., allergens) identified and treated, and patients must be generally compliant with therapies. Although these criteria may not be satisfied in individuals using EDs for asthma, important insights into the mechanisms of severe asthma influence emergent care in this important subgroup.

Cellular features of severe asthma include persistent eosinophilic inflammation that is unresponsive to high-dose corticosteroids along with the presence of neutrophilic inflammation in the distal airways. The latter is not seen in milder forms of asthma but is similar to that of other inflammatory conditions (rheumatoid arthritis, ankylosing spondylitis, Crohn’s disease).
and is associated with greater airway tissue destruction and remodeling with changes suggestive of ongoing epithelial injury and repair.\textsuperscript{127,129} Tumor necrosis factor alpha (TNF-α), an inflammatory cytokine produced by mast cells, is present in increased concentration in bronchoalveolar lavage fluid of patients with severe asthma. Treatment with the TNF-α antagonist etanercept decreases the expression of membrane-bound TNF-α by peripheral blood monocytes, improves airway hyperresponsiveness, FEV\textsubscript{1} and asthma-related quality of life, and may be a future therapeutic target for this subset of asthmatics.\textsuperscript{130,131}

Clinical features of severe asthma (compared with mild to moderate disease) include a lesser prevalence of atopy, a history of aspirin sensitivity, and a higher incidence of sinusitis and use of nasal corticosteroids (suggesting involvement of the upper as well as lower respiratory tract). Exacerbations are also associated with menses.\textsuperscript{132} Other clinical features that distinguish severe asthma from milder forms are being identified in order to focus therapy in this small but important group of asthmatics.\textsuperscript{133}

\textit{Status asthmaticus} refers to severe bronchospasm that does not respond to aggressive therapies within 30 to 60 minutes. \textit{Near-fatal asthma} is identified by respiratory arrest or evidence of respiratory failure (PacO\textsubscript{2} > 50 mm Hg).\textsuperscript{134}

Two types of near-fatal asthma are recognized. Slow-onset near-fatal asthma typically reflects a gradual deterioration of asthma symptoms over several days, usually superimposed on chronic poorly controlled asthma. Rapid-onset near-fatal asthma is characterized by symptom onset and progression to life-threatening status in 3 hours or less. Clinically, rapid-onset near-fatal asthma is characterized by greater hypercapnia than occurs in the slow-onset type. Interestingly, the hypercapnia in rapid-onset near-fatal asthma is more responsive to therapy than that in the slow-onset type, and these patients require shorter durations of mechanical ventilation. Deaths associated with the slow-onset mechanism are thought to be preventable in many cases because the gradual progression of symptoms allows patients to seek medical evaluation before succumbing.

Risk factors for death from asthma are identified (see Box 71-2). Other risk factors linked to near-fatal and fatal asthma include a decreased use of corticosteroids,\textsuperscript{135} hospital admission for asthma treatment within the past 12 months, low socioeconomic status (related to increased allergen exposure and less access to health care), environmental exposures (air pollution, cigarette smoking), and psychosocial and emotional problems. Patients with an episode of near-fatal asthma are also likely to depend on EDs for asthma crisis management. Patients who succumb to fatal asthma commonly tend to be African American, live in inner-city areas, and are between 15 and 34 years of age. Most deaths occur outside or on the way to the hospital, at night, and within 24 hours of the onset of symptoms.

### Clinical Approach to the Critically Ill Asthmatic

The critically ill asthmatic appears agitated (hypoxicemic), assumes an upright position, and appears to be in severe respiratory distress. Tachypnea, diaphoresis, and accessory muscle use are evident. Speech is fragmented into single or short bursts of syllables or words. Absence of wheezing indicates severe expiratory obstruction and minimal air movement. Peak expiratory testing is difficult for the patient to perform but, when possible, indicates severe expiratory obstruction. Alterations in consciousness and bradypnea indicate hypercarbia and impending respiratory arrest.

No laboratory markers identify patients with near-fatal asthma. In critically ill patients, elevated lactic acid levels reflect tissue hypoxemia and anaerobic metabolism; persistent elevations of arterial lactate levels are often associated with a poor prognosis. An elevated lactate level is not predictive of respiratory failure in critically ill asthmatics, and blood lactate levels are not informative.

**Noninvasive Strategies.** Therapies must be initiated immediately (see Table 71-2). Attempts to abort the episode should include high-dose frequent or continuously nebulized beta\textsubscript{2}- and anti-cholinergic agents. If parenteral adrenergic therapy is desired, terbutaline is preferred because of its beta\textsubscript{2} selectivity. IV use of magnesium sulfate or beta\textsubscript{2}-agonists (where available) may be of benefit. Oral prednisone, 60 mg, or IV methylprednisolone, 125 mg, should be administered early. Use of a helium/oxygen delivery system (heliox) is controversial. Helium is an inert gas with one eighth the density of nitrogen. When 60 to 80% helium is blended with 20 to 40% oxygen, the resulting gas mixture has a threefold reduction in density compared with air. Heliox reduces the resistance associated with gas flow through airways with nonlaminar flow and reduces respiratory muscle work; it also increases the diffusion of carbon dioxide and may improve alveolar ventilation.\textsuperscript{136} Although heliox is not intrinsically therapeutic, it may decrease the work of breathing long enough to abort intubation by allowing bronchodilators and anti-inflammatory agents to achieve their effects. Studies have claimed beneficial effects when heliox is used to drive nebulized beta\textsubscript{2}-agonist therapies in both children and adults.\textsuperscript{137,138} No data indicate that heliox reduces the need for intubation or hospital admission, length of hospital stay, or mortality rates.\textsuperscript{136-141} Heliox is administered by nonrebreather mask and may be an adjunctive strategy to mechanical ventilation in selected asthmatics. Close monitoring of oxygen saturation and continuous capnography are advisable. Considerations for heliox include cases of severe airflow obstruction (PEFR <30% predicted and a rapid onset of symptoms <24 hours), a history of labile asthma or previous intubation, and inability to be adequately mechanically ventilated.\textsuperscript{142} Heliox use is discontinued when clinical improvement occurs.

**Noninvasive positive-pressure ventilation** may benefit carefully selected patients (see Chapter 2). Continuous positive airway pressure improves oxygenation and reduces respiratory muscle fatigue by increasing functional residual capacity and lung compliance and supplying some of the inflating pressure required during inspiration. Biphasic positive airway pressure
(BiPAP) provides continuous positive airway pressure but delivers higher pressure during inspiration than expiration. BiPAP is well tolerated by children with status asthmaticus and may decrease the need for intubation and mechanical ventilation.\(^{142}\) BiPAP may also decrease the need for intubation and ICU care in adults with status asthmaticus, although the literature is not conclusive.\(^{143-146}\)

BiPAP is not a substitute for endotracheal intubation and mechanical ventilation. Patient considerations for BiPAP include an alert mental status and intact airway reflexes. Providers should be familiar with BiPAP use in other medical conditions (e.g., COPD, CHF) and close monitoring of consciousness and vital signs is mandatory. Frequent ABG monitoring after institution of this therapy identifies nonresponders. Endotracheal intubation should be performed immediately if respiratory distress persists or if clinical or laboratory signs of deterioration are observed.

Ketamine is an IV dissociative anesthetic with potent bronchodilator effects. Some case reports and small series have suggested benefit when used in acute asthma, but no randomized trials have been conducted. Adverse effects include increased airway secretions and emergence reactions. At present, ketamine is not recommended for therapy of acute asthma in the nonintubated patient.

**Intubation and Ventilator Strategy.** Endotracheal intubation is required in 2% of all asthma exacerbations and 10 to 30% requiring ICU admission.\(^{147-149}\) With the exception of apnea or coma, there are no absolute indications for intubation in the asthmatic patient, but intubation should occur in the failing patient before the patient develops profound acidemia or hypoxemia. Exhaustion, hypoxemia, and depression of mental status strongly mandate prompt intubation.

 Orotracheal rapid sequence intubation utilizing induction agents and muscle paralysis is preferred (see Chapter 1). Ketamine (1–2 mg/kg) is the preferred agent for induction in rapid sequence intubation of the asthmatic patient. Succinylcholine (1.5 mg/kg) or a competitive neuromuscular blocking agent, such as rocuronium (1 mg/kg) can be used for intubation paralysis. Pretreatment with lidocaine (1.5 mg/kg), given 3 minutes before the succinylcholine and ketamine, may mitigate the exacerbation of bronchospasm by the upper airway instrumentation and the endotracheal tube. After intubation, additional ketamine may be given as a small number of intermittent boluses of 0.5 to 1.0 mg/kg, and a benzodiazipine should be administered to keep the patient sedated and to prevent a ketamine emergence reaction. Alternatively, propofol (1.5–2 mg/kg) offers rapid-onset deep sedation and also possesses bronchodilating properties. Continued deep sedation with propofol or an equivalent agent (e.g., long-acting benzodiazipine) usually avoids the need for muscle paralysis. After intubation, an opioid that does not release histamine, such as fentanyl, can be used to improve the patient’s comfort with the ventilator.

 A ventilator strategy providing adequate oxygenation and ventilation while minimizing high airway pressure, barotrauma, and systemic hypotension must be instituted. The technique of *permissive hypercapnia* (also known as controlled hypoventilation) is common (see Chapter 2). Oxygenation is maintained by using a high fraction of inspired oxygen (F\textsubscript{IO\textsubscript{2}}); hypercapnia and respiratory acidosis (pH maintained at 7.15–7.2 using sodium bicarbonate) are tolerated. Airway pressure is kept low by providing low tidal volumes (6–8 mL/kg), thus preventing excessive increases of intrinsic positive end-expiratory pressure, stacking of ventilations, and barotrauma. Low ventilation rates (<10 breaths/min) and high inspiratory flow rates provide prolonged time for expiration. Adjunctive therapies (in-line beta-agonists and anticholinergics, IV corticosteroids, IV ketamine, and possibly magnesium) to decrease airway pressure and airway obstruction are delivered simultaneously.

Continuous capnography is advisable. Moderate levels of hypercapnia are well tolerated and have few deleterious effects. Elevated CO\textsubscript{2} levels have vasodilatory effects on cerebral vessels. Cerebral blood flow reaches its maximum at a PaCO\textsubscript{2} level of 120 mm Hg, which may increase intracranial pressure. Although there is no consensus on what constitutes a safe level of hypercapnia, PaCO\textsubscript{2} levels above 100 mm Hg should be avoided.\(^{148}\) Hypercapnia can decrease cardiac contractility and produce cardiovascular collapse; thus, permissive hypercapnia should be supplemented by generous repletion of intravascular volume through IV fluid administration.

Neuromuscular blockade, once widely used for ventilation of asthmatic patients, is now used only in cases where deep sedation with adequate analgesia fails to provide sufficient patient relaxation for successful mechanical ventilation (see Chapter 1). Myopathy attributed to the prolonged use of competitive neuromuscular blocking agents occurs in about 30% of asthmatic patients with neuromuscular blockade.\(^{147}\) Intubation and mechanical ventilation may be lifesaving in near-fatal asthma attacks. Although hazards of mechanical ventilation (nosocomial infection, barotrauma) may occur, the treatment of critically ill asthmatics with mechanical ventilation is associated with low or zero mortality and few complications. Most asthmatics requiring mechanical ventilation improve rapidly and require short ICU stays.

Complications of mechanical ventilation in the asthmatic patient include hypotension and barotrauma. Hypotension is almost uniformly secondary to increased intrathoracic pressure with a subsequent decrease in venous return and cardiac output. Pneumothorax should be considered whenever sudden clinical deterioration occurs or when hypotension is accompanied by a significant rise in peak inspiratory ventilator pressures and falling oxygen saturation.

**Treatment of the Refractory Critically Ill Asthmatic.** If the intensively treated, intubated critically ill asthmatic continues to have elevated airway pressures, persistent hypoxemia, and continued bronchospasm, general anesthesia should be considered in the operating room. Isoflurane, a bronchodilator, has lower arrhythmogenic and hypotensive properties than halothane.\(^{150}\)

External lateral chest compression may be of assistance when patients cannot exhale. Chest compression is delivered by bilateral squeezing of the lower chest walls immediately after end inspiration occurs. Compression delivered too early (i.e., during inspiration) may increase airway pressure and result in barotrauma. In children, this technique decreases peak airway pressure and PaCO\textsubscript{2} and increases pH.\(^{151}\)

Cardiopulmonary arrest may result from unrecognized barotrauma. Empirical bilateral tube thoracostomy should be performed if unexplained cardiac arrest occurs, especially in the context of dramatic increases in peak inspiratory pressure. IV ephedrine is a logical agent to use in the setting of cardiopulmonary arrest because it has both cardiotonitory and bronchodilatory properties.\(^{152}\) Isoproterenol, a pure beta-agonist, may increase heart rate and provide bronchodilation, but it decreases coronary perfusion pressure. Cardiopulmonary bypass and extracorporeal lung assist are also used in the treatment of near-fatal asthma.

### DISPOSITION

**Prediction of Relapse**

Asthmatic patients discharged from the ED have rates of relapse that vary from 11% over 3 days to 45% at 8 weeks. In
in a multicenter study, the relapse rate was 17% in the 2 weeks after ED discharge. The risk for relapse increases in those with numerous asthma-related ED visits within the last year, with more outpatient medications and with longer duration of symptoms before the ED visit. Other studies find similar out-of-control indices predicting relapse but have also included insufficient improvement in PFTs with hospital-based treatment for an attack.

### Inpatient versus Observation or Clinical Decision Unit

Patients requiring extended care who are without life-threatening exacerbations, pregnancy, or complications of asthma can generally be treated in a clinical decision unit (CDU) for 12 hours with 8-week outcomes equal to those of patients treated in a hospital ward but with significant cost savings. The ability to predict discharge from the CDU can be assessed by the ED PEFR response to the third beta2-agonist treatment (PEFR > 40% predicted is often associated with successful CDU discharge). Lastly, patients prefer CDU treatment of acute attacks over routine inpatient care.

Table 71-4 summarizes disposition guidelines for asthmatics on the basis of their response to therapies in the ED.

### Planning Discharge from the Emergency Department

An asthma exacerbation does not end on ED discharge; airway inflammation and peripheral obstruction may take hours to days to resolve. Patients are likely to need continued beta2-agonist rescue therapy during this time, and it is important that they can demonstrate the correct use of their inhalers. If the patient is having difficulty coordinating the canister activation with inhalation, a breath-activated inhaler or spacer device must be prescribed or the need for a home nebulizer discussed. A patient using a portable, preloaded, multidose dry-powder inhaler must be able to inhale from the mouthpiece in a rapid and forceful inhalation to total lung capacity.

Patients receiving systemic corticosteroids in the ED must continue these orally for 5 to 10 days. Asthma patients treated in the ED are more likely to have moderate to severe disease; not receive controller therapy; and be younger, poorer, and less educated. They have reduced asthma management skills and are more likely to miss school or work. If the patient is not using controller medications and experiences persistent disease, moderate-dose inhaled steroids or a combination inhaled steroid and long-acting beta-agonist (e.g., salmeterol xinafoate-fluticasone propionate) should be started. A less preferred option is to prescribe an ILT modifier (e.g., zafirlukast 20 mg twice a day or montelukast 10 mg daily) to decrease relapse and improve asthma control.

Patients should be encouraged to contact their physician or a respiratory specialist nurse for asthma-related problems within the next 3 to 5 days and to make a follow-up medical appointment within 1 to 4 weeks. At this visit it can be decided whether the control drug regimen needs to be adjusted. Interventions that include free medications, transportation vouchers, and appointment assistance significantly increase the likelihood that discharged asthma patients will obtain primary care follow-up. These assistances, however, may not affect long-term outcomes. Since the follow-up visit with a primary care physician does not ensure the prescribing of ICS, emergency physicians must evaluate chronic asthma management.

The asthma patient can be provided written education about discharge medications, medication adjustment if the condition is not improving, and a peak flow meter for daily measurements, especially for those who have difficulty perceiving airflow obstruction or who have symptoms of worsening asthma. Lastly, smoking is surprisingly common (up to one third) in asthmatics presenting to the ED, and smoking asthmatics have more respiratory symptoms, lower lung function, and more parenchymal abnormalities noted on chest computed tomography.

CDU, clinical decision unit; FEV1, forced expiratory volume in 1 second; PEFR, peak expiratory flow rate.
IgE-mediated immune responses, airway inflammation, and airway remodeling are concepts crucial to our understanding of asthma and are the targets of current and future therapies.

Inhaled and systemic steroid medications are effective in controlling airway inflammation and have important roles in management of asthma exacerbations.

Single-isomer albuterol (levalbuterol), the result of improving isomer technology, is a better bronchodilator in acute asthma than the traditional racemic form.

Severe and refractory asthma exacerbations require rapid identification. Treatment must be aggressive and may employ strategies not used in mild to moderate exacerbations.

The ED’s management of acute asthma is expanding (up to 24 hours) as more noncritically ill asthmatics are treated in the clinical decision units.

Integration of discharged acute asthmatics into chronic management strategies to prevent relapse requires that asthma patients’ physicians be familiar with controlling medications such as ICSs and LT modifiers.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
**PERSPECTIVE**

Chronic obstructive pulmonary disease (COPD) is one of the most common causes of death worldwide. Epidemiologists agree that the prevalence of COPD is underreported and that its burden is increasing. Regardless of the success of smoking cessation programs, smoking behavior in the past several decades and the delay of the appearance of symptoms in an aging population virtually guarantee an increase in prevalence. Although in the United States the mortality rate among men is leveling off, the rate for women is still increasing. It has been estimated that COPD will be the seventh leading cause of lost disability-adjusted life years (DALYs) worldwide by 2030. The financial burden of COPD is enormous, accounting for billions of dollars every year for treatment and lost productivity. The majority of these costs are related to hospitalization for acute exacerbations. Despite its enormous effects, COPD has received relatively less attention from basic medical researchers and clinicians than other diseases. This trend has begun to reverse. Large multinational collaborations, such as the Global Initiative for Chronic Obstructive Lung Disease (GOLD) sponsored jointly by the National Heart, Lung, and Blood Institute and the World Health Organization, are designed to help reinvigorate the scientific and medical communities frustrated by the unrelenting progressive nature of COPD and its poor response to existing therapies.

The definition of COPD is imprecise and incorporates advances in our understanding of its underlying mechanisms and natural history. In their consensus statement, the GOLD collaborators define COPD as “a preventable and treatable disease with some significant extrapulmonary effects that may contribute to the severity in individual patients. Its pulmonary component is characterized by airflow limitation that is not fully reversible.” They also state that “the airflow limitation is usually progressive and associated with an abnormal inflammatory response of the lungs to noxious particles or gases.” This definition reflects new data underscoring the systemic nature of the disease, as well as a deliberate optimism with respect to new prevention and treatment strategies. It specifically avoids mention of chronic bronchitis and emphysema, two entities that have been traditionally included in the definition of COPD. Chronic bronchitis, defined as the presence of cough and sputum production for at least 3 months in each of two consecutive years, can occur without airflow limitation. Emphysema, the destruction of alveoli, is a pathologic term, not one that pertains to clinical diagnosis. Unlike many earlier definitions of COPD, the GOLD collaborators also specifically exclude asthma, which is reversible airflow limitation. Whether reversible airflow limitation is considered to be part of COPD itself or due to coexisting asthma is of limited significance to the emergency physician, who will continue to make every attempt to identify and reverse airflow limitation.

As many as 50% of all acute COPD exacerbations are not reported to physicians. In addition, not all reported exacerbations require hospitalization. Nonetheless, in 1998, almost 2% of all hospital admissions in the United States were directly attributed to COPD, and it was considered a contributory factor in another 7%. In patients older than 65, the percentage of all hospitalizations related to COPD approaches 20%. As the severity of the underlying disease progresses, so does the frequency of exacerbations. Moreover, in a subset of patients, incomplete recovery from acute exacerbations may reflect a contribution of exacerbations to the pathophysiology of relentless disease progression.

**PRINCIPLES OF DISEASE**

**Pathophysiology**

In the past two decades, the discovery that chronic airway inflammation plays a central role in the pathophysiology of asthma led to an important change in its management, specifically, the liberal use of corticosteroids for treating moderate to severe disease. Airway inflammation is also at the center of the pathophysiology of COPD, but the inflammatory process of COPD differs from that of asthma. In COPD, neutrophils, CD8+ lymphocytes, and macrophages predominate in bronchial washings, whereas in asthma, the cellular response is characterized by the presence of eosinophils. The inflammatory mediators differ in COPD, and several mediators, such as tumor necrosis factor, leukotriene B4 (LTB4), and interleukin-8 (IL-8), are linked to the destruction of parenchyma. These differences in the nature of the inflammatory response in COPD may account for its relatively poor response to current anti-inflammatory treatment compared with asthma.

Pathologically, the abnormalities in COPD are found throughout the lungs. Although certain changes may be more or less prominent in a given patient, most patients have at least some component of the two main pathologic entities: chronic obstructive bronchitis and emphysema. Evidence of airway inflammation is found from the trachea down to the smallest...
peripheral airways, which become progressively scarred and narrowed. An increase in both the number and size of mucus-secreting goblet cells results in the formation of mucous plugs that further contribute to airflow obstruction. Damage to the endothelium impairs the mucociliary response that clears bacteria and mucus. The lung parenchyma is progressively destroyed over time, usually in a pattern of centrilobular emphysema. This consists of a destruction of alveoli, loss of lung elasticity, and the closure of small airways, which rely on the radial support of surrounding connective tissues to maintain their patency during expiration.

The combination of airway obstruction and obliteration of the pulmonary vascular bed results in a failure of gas exchange. Thus, arterial blood gases (ABGs) may reveal both hypoxemia and hypercapnia. As the overall size of the pulmonary vascular bed decreases with time, chronic hypoxia induces a thickening of the vessel walls. Both of these factors contribute to the development of pulmonary hypertension, polycythemia and, eventually, right-sided heart failure (cor pulmonale).6,12,13

The pathophysiology of COPD reflects the apparent imbalance between proteases and antiproteases that favors the destruction of connective tissue in the lungs. In one small subset of COPD patients with congenital α1-antitrypsin deficiency, a lack of α1-antitrypsin, an enzyme that inhibits neutrophil elastase, leads to the pathology of severe panacinar emphysema.14 In the majority of patients, however, the specific genetic factors are less well elucidated.15,16 Oxidative stress, the imbalance of oxidant to antioxidant activity in favor of oxidants, is another important facet of the pathophysiology of COPD. External oxidants are found in cigarette smoke, whereas the products of the inflammatory process result in intrinsic oxidants. Not only may oxidants cause direct parenchymal damage, but oxidative stress indirectly fuels further inflammation and protease activity.17

Cigarette smoking, the most significant risk factor for the development of COPD, exerts its effects at multiple points in the inflammatory cascade of COPD, negatively affecting both the protease to antiprotease and oxidant to antioxidant balances.12,17,18 Although smoking cessation slows the progression of the disease, it does not end the chronic inflammatory process within the airways, indicating that mechanisms independent of smoking are involved.12 Moreover, although a majority of COPD patients have a significant smoking history, only a minority of smokers ever develop airflow limitation. This suggests the importance of other factors, both environmental and genetic.19 Other identified causative factors include heavy occupational exposure to dusts and air pollution from indoor cooking, particularly in the developing world.16,22 Long-term passive exposure to tobacco smoke also appears to be contributory, but the role of urban air pollution is not established.23 Although there is an association between early childhood lower respiratory tract infections and later development of COPD, a causal relationship is less certain.24-27

Compensatory physiologic responses in COPD vary according to the balance of underlying pathologic derangements seen in individual patients. In a minority of patients, ventilatory drive is increased to maintain a near normal partial pressure of oxygen (P02), preventing any cyanosis. The resultant tachypnea may also cause a slightly low partial pressure of carbon dioxide (PCO2). In such patients with relatively normal blood gases, pulmonary hypertension and cor pulmonale may not occur until very late in the course of the disease.

Although the precise mechanisms are ill-defined, the pathologic processes of COPD extend beyond the cardiac and pulmonary systems. The effects of circulating inflammatory mediators, oxidative stress, and protease antiprotease imbalance may be responsible for the weight loss, muscular wasting, metabolic derangements, and depression often seen in the later stages of disease.28,29,30 These features of COPD are partly responsible for the influence of COPD as a comorbid illness, even when the presenting complaint is nonpulmonary. COPD influences a variety of management decisions in the emergency department (ED), ranging from the choice of agents for procedural sedation and rapid sequence intubation to the appropriate disposition of patients with nonpulmonary diagnoses.

### Staging the Severity of Disease

Most classifications of disease severity are based on quantitative measurements of airflow limitation, such as the forced expiratory volume in 1 second (FEV1) and FEV1/forced vital capacity (FVC) ratio. These indices are measured after any reversible airflow limitation is addressed by treatment with bronchodilator medications. The GOLD collaborators define four stages, beginning with a mild stage (stage 1), when spirometry is abnormal, but symptoms may not yet be apparent, and ending in very severe COPD (stage 4), when FEV1 is less than 30% of predicted (Table 72-1). Frequent exacerbations are usually seen when the FEV1 falls below 50% predicted (stages 3 and 4).30

COPD, chronic obstructive pulmonary disease; FEV1, forced expiratory volume in 1 second; FVC, forced vital capacity; Pao2, arterial partial pressure of carbon dioxide; Paco2, arterial partial pressure of oxygen; SOB, shortness of breath.

### Acute Exacerbations

Unlike asthma exacerbations, COPD exacerbations are not necessarily associated with major reductions in peak flow and FEV1 measurements. Like COPD itself, the definition of an acute exacerbation is imprecise and relies on clinical parameters that are often subjective. The definition adopted by the GOLD collaborators is “an event in the natural course of the disease characterized by a change in the patient’s baseline dyspnea, cough, or sputum that is beyond day-to-day variations, is acute in onset, and may warrant change in regular medication in a patient with underlying COPD.”31
Acute exacerbations are more common in the winter months, which most likely reflects the importance of viral pathogenesis. As with asthma, viral infection appears to be a frequent inciting agent in COPD exacerbations. Commonly implicated viruses include rhinovirus, respiratory syncytial virus (RSV), coronavirus, and influenza virus.\(^{31-33}\) Exacerbations associated with a viral etiology are longer and more severe than those without an apparent inciting agent.\(^{33,34}\)

Controversy remains regarding the role of bacterial pathogens in acute exacerbations of COPD, since the evidence for the role of bacteria in the pathogenesis remains indirect. Almost one half of all exacerbations are associated with negative cultures for the typical respiratory pathogens such as *Haemophilus influenzae*, *Streptococcus pneumoniae*, *Moraxella (Branhamella) catarrhalis*, and *Pseudomonas aeruginosa*. In addition, these organisms are recovered from the tracheobronchial tree of patients in their chronic, steady state, suggesting that bacteria may play a more important role in the pathogenesis of chronic COPD than in acute exacerbations.\(^{35-38}\) Although molecular typing shows that recent colonization with new serotypes of the common pathogens is associated with an exacerbation, there is a possibility that this relationship is not causal.\(^{35,38,39}\) Experimental evidence of specific immunologic responses to bacteria in exacerbations suggests, however, that they do play a significant role.\(^{40,41}\)

Environmental factors, such as air pollution, are also implicated in COPD exacerbations. Indirect evidence for this relationship is largely derived from hospitalization rates for exacerbations during periods of increased air pollution.\(^{42}\) Finally, in as many as one third of all COPD exacerbations, no specific cause can be identified.\(^{43}\)

In addition to acute exacerbations, patients with COPD may present with worsening symptoms due to comorbid conditions such as pneumonia, congestive heart failure (CHF), pneumothorax, pulmonary embolism (PE), lobar atelectasis, pleural effusion, or dysrhythmias. All of these are associated with COPD and may mimic or coexist with an acute exacerbation.

**CLINICAL FEATURES**

**Symptoms and Natural History**

COPD patients have a long premorbid course during which decreases in airflow indices can be measured in the absence of early symptoms. Intermittent cough or shortness of breath on exertion may be easily misattributed to poor physical conditioning. Moreover, patients may remain asymptomatic for many years by gradually limiting their activities in proportion to their pulmonary reserve. After several years, a daily productive cough frequently develops and periods of dyspnea, the cardinal symptom of airflow limitation, increase. The clinical progression of COPD is slow and insidious, with gradual decreases in airflow punctuated by increasingly frequent and debilitating exacerbations. Eventually, the patient becomes truly incapacitated by dyspnea on minimal or no exertion. Profound muscle wasting and weight loss and the emergence of cor pulmonale or chronic ventilatory failure are characteristic of end-stage disease. Figure 72-1 depicts the progression of COPD over time.

**Physical Examination**

The division of patients with COPD into two phenotypes, the “blue bloater” (for the patient with chronic obstructive bronchitis) and the “pink puffer” (for the patient with emphysema), is outdated because many patients with COPD do not conform to these descriptions. Nonetheless, these classical images do highlight some of the important clinical features that may be encountered in the patient with COPD and have implications for management. Most patients present with some combination of chronic obstructive bronchitis and emphysema and appear with a mixture of the syndromes described below. The precise identification of which process is predominant is less important than the evaluation of each patient and formulation of a specific treatment plan based on the individual clinical findings. In particular, the degree of chronic hypoxemia and dependence on home oxygen therapy, the presence of cor pulmonale, and evidence of comorbid illness, such as ischemic heart disease, should be determined.

In patients in whom chronic obstructive bronchitis predominates, the findings are those of chronic respiratory failure and cor pulmonale. Little air hunger or anxiety is present, and the combination of polycythemia and hypoxemia creates a palesotic, cyanotic appearance. Cough, as the clinical hallmark of bronchitis, is prominent and, when vigorous, causes expectoration. If acute ventilatory failure is present, the patient’s consciousness is clouded. This often can be described as “irritable somnolence,” and asterixis may be present. Chronic ventilatory failure and cor pulmonale account for the prominent peripheral edema and chronic jugular venous distention. If there is relatively little emphysema, the thoracic anteroposterior diameter is normal and the diaphragm is not abnormally low. The presence of severe bronchopulmonary secretions is evidenced by scattered rhonchi and rales, especially at both lung bases posterolaterally. These patients often have chronic CO\(_2\) retention, requiring close monitoring of O\(_2\) therapy because of their relative dependency on hypoxic drive for ventilation.

When emphysema predominates, the patient is often thin, anxious, alert and oriented, dyspneic, tachypneic, and utilizing accessory muscles of breathing. The patient often self-administers positive end-expiratory pressure (PEEP) by using a pursed lip exhalation pattern to increase intraluminal bronchial pressure and provide internal support for bronchial walls that have lost their external support. Such patients usually assume a sedentary existence, chronically hunched forward.

![Figure 72-1. The progression of COPD over time.](image-url)
Gross lung overinflation occurs, with a low immobile diaphragm and an increased anteroposterior diameter of the thorax. Percussion of the chest reveals hyper-resonance, and auscultation demonstrates diminished breath sounds with faint end-expiratory rhonchi. Despite air hunger caused by the extensive lung parenchyma destruction, the patient maintains adequate oxygen saturation and often has near-normal ABG levels. The heart is small and hypodynamic, and the blood pressure is usually low.

Cardiac examination in a patient with suspected COPD is crucial in the diagnosis of cor pulmonale and coexisting left ventricular failure. A subxiphoid or retrosternal heave suggests chronic right ventricular hypertrophy (RVH), an S₃ suggests decreased left ventricular compliance, an S₄ indicates left ventricular failure, and a holosystolic blowing murmur of tricuspid insufficiency is secondary to right ventricular and tricuspid ring dilation. Accentuation of the pulmonic component of the secondary sound reflects pulmonary hypertension. Chronic visceral congestion causes hepatomegaly, hepatojugular reflux, and sometimes prominent abnormalities of liver function.

■ DIAGNOSTIC STRATEGIES

Pulse Oximetry, Arterial Blood Gas Analysis, and Waveform Capnography

Pulse oximetry is part of the evaluation and monitoring of every patient with a COPD exacerbation. Comparison with prior values, both in crisis and in baseline state, helps to interpret measurements obtained during an acute exacerbation. The change in pulse oximetry from baseline or in response to emergency therapy is generally more important than absolute levels.

The stages of COPD severity correlate with arterial gas tensions. Abnormal ventilation-perfusion relationships of COPD produce only modest decrements in PaO₂ in its early stages (80–100 mm Hg). Later in the course of the disease, hypoxemia below 60 mm Hg stimulates respiratory centers, producing hyperventilation (PCO₂ < 35) and acute respiratory alkalosis. As pulmonary dysfunction progresses, the work of hyperventilation becomes cost-ineffective; that is, more CO₂ is produced by the effort than is cleared by the increased ventilation. Eventually, alveolar hypoventilation impairs gas exchange, leading to CO₂ retention and acute respiratory acidosis. With renal compensation through bicarbonate retention, the pH normalizes. Finally, when acute ventilatory superimposed at this stage of the disease, an elevated PaCO₂, lowered pH, and elevated bicarbonate are found.

ABG values, once a mainstay of ED evaluation of COPD patients, are of limited value. A direct measurement of ABGs may be considered in patients with severe exacerbations for whom hospitalization is anticipated. The presence of respiratory failure unresponsive to therapy (defined as PaO₂ < 40 mm Hg, PaCO₂ > 60 mm and pH < 7.25 Hg) warrants consideration of admission to an intensive care unit, but clinical evaluation is much more important than any particular blood gas values. When baseline blood gas levels are not available, the utility of the ABGs is even more limited, and interpretation should be based on the degree of acidosis present, which likely represents the extent of acute CO₂ retention. ABGs should not be used to determine whether a patient requires intubation or noninvasive ventilatory support (NIVS). These decisions should rather be guided by the overall state of the patient, progression of fatigue, comorbid illness, and response to therapy. Patients with very poor blood gas values may do well without intubation or NIVS, but others with mildly disturbed values may require urgent airway intervention. Thus, ABGs should not be performed routinely in the ED and should only be undertaken in response to specific circumstances, such as irregular or apparently unreliable pulse oximeter values.

Waveform capnography represents the continuous quantitative measurement of exhaled CO₂. It has emerged as a potential diagnostic and monitoring tool in patients with acute respiratory distress. The appearance of the waveform may assist the clinician in differentiating acute exacerbation of COPD from other causes of acute dyspnea such as CHF. In patients with obstructed airways, the plateau phase of the waveform typically steepens in proportion to the severity of the obstruction. Unfortunately, in patients with COPD, the actual end-tidal PCO₂ measurements obtained from capnography do not correlate well with arterial PCO₂ measurements, especially in more severe disease. Nonetheless, the patterns and trends from capnography may be helpful in guiding management.⁴⁵

Chest Radiography

In patients who are known to have COPD, the primary role of the chest radiograph is to determine whether there is an acute, treatable cause for clinical deterioration, especially pneumothorax or parenchymal consolidation (atelectasis secondary to mucus plugging, pneumonia, or obstruction by tumor). Otherwise, the chest radiograph is of limited use and may exhibit a range of chronic changes, depending on disease severity and the relative degree of the various pathologic processes. Findings may include hyperinflated lung fields, decreased vascular markings, and a small cardiac silhouette, or, in contrast, normal inflation, with increased vascular markings and an enlarged heart.⁴⁶ In cor pulmonale, impingement on the retrosternal airspace by the enlarged right ventricle can be seen on the lateral film.

Bullae may also be present and resemble or mask a pneumothorax. In addition, chest radiography may reveal important coexistent pathology including CHF, effusions, and tumors. Routine chest radiography, although challenged, is appropriate in patients with acute exacerbations of COPD.⁴⁵⁷

Forced Expiratory Volume and Peak Expiratory Flow Rate

Pulmonary function tests (PFTs) are more useful in asthma, where there is a significant reversible component of airway obstruction. In addition, the patient in acute respiratory distress is often unable to cooperate, making testing unreliable. Thus, PFTs add little to decision making in cases of acute COPD exacerbation.

Sputum Examination

During acute exacerbations of bronchitis, sputum may be thicker and grossly purulent, but neither Gram’s stain nor culture of sputum has been shown to be of value in acute COPD exacerbation.⁴⁶

Electrocardiogram and Cardiac Monitoring

The classic descriptions of P pulmonale (peaked P waves in leads II, III, and aVF), low QRS voltage, clockwise rotation, and poor R wave progression in the precordial leads are interesting correlates of COPD but are both insensitive and nonspecific. The presence of electrocardiogram (ECG) criteria for RVH suggests established cor pulmonale. These findings,
however, can be easily obscured on the ECG by other processes and the absence of criteria for RVH cannot be relied on to rule out cor pulmonale.49

In severely ill patients, or those with concomitant chest pain, continuous ECG monitoring may be helpful, at least for the initial phase of the patient’s evaluation and treatment. ECG monitoring can detect dysrythmias associated with COPD exacerbations and changes of rate and rhythm in response to therapy. The most common dysrythmias associated with COPD are atrial tachydysrhythmias, such as atrial fibrillation and multifocal atrial tachycardia. Although atrial fibrillation may require treatment with rate control or conversion, multifocal atrial tachycardia often resolves with the treatment of the COPD exacerbation itself.50

**Blood Tests**

Routine hematologic evaluation adds little to the treatment of the patient with COPD and acute exacerbation. A complete blood count may reveal polycythemia associated with chronic hypoxia. An elevated white blood cell (WBC) count is nonspecific and should not be interpreted as indicative of coexistent infection; nor should a normal range WBC count support a contention that no infection is present. Elevations in WBCs in COPD are more often related to the hyperadrenergic state of acute dyspnea. Although its use has declined markedly in recent years, if the patient is on a theophylline preparation, obtaining a theophylline level is warranted since many patients take additional medications when their breathing deteriorates, and toxicity may be seen. Patients may have symptoms or effects of theophylline toxicity even with a “normal” level, since the therapeutic margin of this agent is so narrow.51

The measurement of B-type natriuretic peptide (BNP) is a tool to differentiate acute CHF from other disease processes, mainly COPD and asthma, that may similarly present with acute dyspnea. BNP is a naturally occurring peptide that is released by the ventricles in response to volume expansion and stretch. It plays a central role in the neurohormonal response to “unload” the ventricles in CHF through natriuresis, diuresis, vasodilation, and suppression of the renin-angiotensin system. It is a sensitive marker for both acute and chronic CHF, and correlates well with the functional class of patients as well as their prognosis.52,53 Both rapid bedside (whole-blood) and plasma assays are available. Using a cutoff value of 100 pg/mL to exclude the diagnosis of CHF, BNP is significantly more accurate in excluding CHF in acutely dyspneic patients than a conventional clinical assessment by general internists and emergency physicians. As the cutoff value is lowered, the assay is more sensitive for detecting CHF, but at the expense of overall accuracy.54 Moreover, the utility of BNP is debated in patients for whom it is most likely to be helpful, such as those with equivocal clinical evaluations.55 Thus, BNP measurements may be helpful in revealing patients with unsuspected CHF, but its role in the management of acute COPD exacerbations is yet to be fully delineated (see Differential Considerations).

**DIFFERENTIAL CONSIDERATIONS**

The differential diagnosis of the acutely dyspneic and hypoxic patient is broad. The condition that is most commonly mistaken for COPD is cardiogenic pulmonary edema, which may present with dyspnea and wheezing (“cardiac asthma”). Other serious cardiac etiologies include myocardial ischemia and pericardial effusion. Important pulmonary diagnoses include pneumothorax, PE, pneumonia, asthma, acute respiratory distress syndrome, bronchiectasis, pulmonary fibrosis, pleural effusions, and tuberculosis. In addition, metabolic acidosis and shock may manifest as dyspnea and ventilatory failure.

In most cases, differentiation of COPD exacerbation from acute CHF can be made on clinical grounds. Nonetheless, a significant percentage of patients presenting to the ED with acute dyspnea and an established diagnosis of COPD are ultimately diagnosed with acute CHF despite having no prior history of heart failure. The addition of a BNP assay to the ED evaluation of such patients likely identifies the majority in whom a new diagnosis of CHF was not suggested.56 Although this strategy will potentially result in a greater number of patients being treated in a timely fashion for CHF, due to the limited specificity of BNP measurements, it will also falsely identify a substantial number of patients as having CHF at any cutoff value used.

Conversely, because of the high negative predictive value of a very low BNP (<100 pg/mL), acutely dyspneic patients with very low BNP values despite a moderate degree of clinical suspicion for CHF should be considered to have COPD.57

Because BNP can be elevated in association with right ventricular stretch, incautious interpretation of an elevated BNP may lead to the clinician to favor the diagnosis of acute left sided CHF and overlook cor pulmonale and PE, both critical considerations in the patient with COPD.52 Moreover, acute CHF and COPD often coexist, and even severe elevations in BNP do not obviate the identification and treatment of acute pulmonary pathology.58 Thus, although BNP measurement may be helpful in the evaluation of the acutely dyspneic patient, it cannot be interpreted in isolation.

Acute pneumothorax can occur with COPD. This diagnosis should be actively pursued in patients presenting with worsening respiratory status, especially when its onset is abrupt. In older patients with COPD, chest pain is often absent. A small pneumothorax cannot be excluded by physical examination and can be very difficult to detect on inspiratory chest films, especially in patients with bullous emphysema. Bedside ultrasound is a useful modality for diagnosing pneumothorax in the ED, particularly in major trauma. The presence of COPD, however, may result in false-positive results, and data in this setting are limited.59 Ultimately, it is appropriate to perform chest computed tomography (CT) when clinical suggestion of a pneumothorax remains high and results of plain films and ultrasound are nondiagnostic.

Patients with COPD are often sedentary, and consequently at increased risk for venous thromboembolic disease.60 The patient with cor pulmonale is at even higher risk because of increased blood viscosity, high peripheral venous pressure, and venous stasis. Pulmonary embolus (PE) should be considered when an acute exacerbation is more severe than prior episodes, particularly if deterioration occurs quickly, with no other apparent cause.61 Unfortunately, because there is significant overlap in their patterns of presentation, differentiating a PE from a COPD exacerbation can be extremely difficult. Prophylactic measures to prevent venous thromboembolic disease are important considerations in the inpatient management of an acute exacerbation of COPD.

A negative screening test with a sufficiently sensitive D-dimer assay (enzyme-linked immunosorbent assay [ELISA] or whole-blood agglutination) excludes venous thromboembolic disease in all but high pretest likelihood situations.62,63 Pretest probability can be assessed using any one of several structured, validated scoring systems. If either the D-dimer is elevated or the pretest probability for PE is high, CT pulmonary angiography should be performed.63 This requires multislice CT capability and may include indirect CT venography to evaluate the lower extremities for deep vein thrombosis or lower limb duplex ultrasonography.64,65 A more detailed discussion
of the diagnostic evaluation and treatment of PE can be found in Chapter 86.

Lobar atelectasis occurs as a result of mucous plugging of bronchi and can be lethal. Similar to pneumothorax and PE, it may present abruptly. The chest film may show linear horizontal streaking or small flarëlike shadows; more often, it is normal. Hypoxemic reactive airway patients with a protracted course unresponsive to bronchodilators should be presumed to have either PE or atelectasis. If PE is excluded, such patients often require endotracheal intubation and aggressive interventional pulmonary toilet.

Pneumonia is a common, devastating complication of COPD that leads to mortality in many patients. Its clinical appearance is more muted than the classically described lobar pneumonia of young adults. Classic symptoms of cough, fever, and toxicity are seen less often than the more nonspecific and subtle symptoms of malaise, weakness, decreased activity, and anorexia.

Leukocytosis may or may not be present, and its presence should not be taken as indicative of infection, because of its low specificity. An infiltrate may or may not be seen, and correlation with previous radiographic studies may be necessary. Rib fractures occur in patients with COPD secondary to trauma, but in patients receiving steroid therapy, they can be due to vigorous cough alone. When rib fractures are identified, secondary pulmonary contusion and pneumothorax must also be considered. An intercostal nerve block may relieve enough discomfort to restore baseline pulmonary function.

Electrolyte disturbances, such as hypokalemia, hypomagnesemia, hypocalcemia, or hypophosphatemia may impair the contractility of muscles.

There are other treatable chronic, nonobstructive pulmonary diseases. For example, bronchiectasis is an often overlooked cause of purulent expectoration. It may accompany and contribute to COPD exacerbations. Although its pathologic characteristic is dilation, not constriction, of airways, the secretions that accompany it may result in an obstructive component. Active tuberculosis must be considered in patients with infiltrates (not only apical), a chronic wasting course, and risk factors for active disease, such as immunodeficiency virus (HIV) disease and homelessness. Sarcoidosis, which can present with chronic cough and constitutional symptoms, usually causes a dry cough and may be suggested on the basis of the chest film appearance.

Finally, there are some iatrogenic causes of acute decompensation in COPD. Many agents, such as beta-blockers and cholinergic agents, may directly or indirectly produce bronchospasm. A second group of potentially deleterious drugs are sedatives. It is important not to confuse hypoxic agitation with anxiety because patients with chronic respiratory failure are abnormally sensitive to the respiratory depressant effect of sedatives, and even small doses may significantly worsen hypoventilation.

Box 72-1 summarizes the causes of acute decompensation in the patient with COPD.

### MANAGEMENT

The only modalities that alter the progression of COPD and reduce mortality rates are smoking cessation and chronic oxygen therapy for those with severe disease. Vaccines, both against influenza and pneumococcus, are another important aspect of ongoing outpatient care. An overview of the emergency assessment and management of COPD exacerbations is provided in Box 72-2.

It is important to consider an inciting or aggravating factor and provide specific therapy as discussed in text.

ABC, airway, breathing, and circulation; COPD, chronic obstructive pulmonary disease; IV, intravenous; MDI, metered dose inhaler.
Ventilation and Oxygenation

All COPD patients in acute respiratory distress need continuous ECG and pulse oximetry monitoring. The patient in terminal ventilatory failure is cyanotic, speechless, lethargic, usually confused, and has gasping, ineffective respirations. Such patients require immediate endotracheal intubation and mechanical ventilation. Since these patients have exhausted all pulmonary reserve, rapid sequence technique should be performed with the goal of rapid paralysis and unconsciousness (see Chapter 1). For induction and paralysis, a combination of a hemodynamically stable sedative-hypnotic such as etomidate and a rapidly acting paralytic such as succinyllcho- line is an appropriate regimen.

Initial ventilator settings should include a fraction of inspired oxygen (FiO₂) of 100%, tidal volume in the 6- to 8-mL/kg range, and respiratory rate of 8 to 10 breaths/minute in an assist control mode with an inspiratory flow rate of 80 to 100 L/minute. Sedation and analgesia are indicated to facilitate ventilation. Neuromuscular blockade is not routinely required and should be avoided when possible (see Chapter 1). Increased air trapping and resultant high intra-alveolar pressures physiologically induces intrinsic positive end-expiratory pressure (iPEEP) that can cause barotrauma. In addition, increased intrathoracic pressure decreases cardiac filling and output; therefore, peak flow pressures and systemic blood pressures must be carefully monitored. If continuous capnography is not available, ABGs should be drawn after 15 to 20 minutes to ensure that ventilation is appropriate. In some settings, placement of an arterial line is helpful for monitoring blood pressure and ABG tensions. After intubation, permissive hypercapnia is essential to the ventilatory treatment of these patients, and subsequent normalization of pH and PaCO₂ should be gradual over many hours. Low volume and rate settings will result in hypercapnia and respiratory acidosis, but this approach helps prevent associated barotrauma often seen in treating these patients. Moreover, hyperventilation alkalosis must be scrupulously avoided, particularly because patients may have preexisting chronic metabolic alkalosis. This alkalosis can result in seizures and dysrhythmias, especially with coexisting hypokalemia.

Noninvasive ventilatory support (NIVS) is an accepted alternative to invasive ventilation in many patients with ventilatory failure (see Chapter 2). NIVS can be highly effective in avoiding intubation, increasing pH, reducing PaCO₂ and dyspnea in the first 4 hours of treatment, and reducing mortality rates. Selection of patients for NIVS continues to be challenging. Patients likely to benefit from NIVS are those with moderate to severe ventilatory failure and elevated PaCO₂, but without marked hypoxemia. NIVS cannot substitute for invasive ventilation in those patients who are hemodynamically unstable or in whom respiratory arrest appears inevitable. On the opposite end of the spectrum, it remains unclear whether NIVS should be instituted in patients with mild to moderate exacerbations. Although the Cochrane Systematic Review stresses early NIVS therapy to prevent the development of worsening acidosis and need for intubation, there is insufficient evidence to recommend the routine use of NIVS in mild exacerbations. Table 72-2 outlines inclusion and exclusion criteria for the use of NIVS.

NIVS can be delivered by either a nasal or a full-face mask. Modes of ventilation include continuous positive airway pressure (CPAP) and biphasic positive airway pressure (BiPAP). Patients with COPD and respiratory distress have significant intrinsic PEEP (iPEEP), and this acts as an inspiratory threshold for the patient and increases the work of breathing. Both modes of NIVS help to counteract this iPEEP and thereby decrease the work of breathing. Nasal CPAP is a simple technique, and 5 to 10 cm H₂O pressure is required. When using BiPAP ventilation, expiratory positive airway pressures are typically set at 2.5 to 5 cm H₂O, while inspiratory pressures range between 7.5 and 15 cm H₂O.

If the patient experiences relief of dyspnea, has stronger respirations, and becomes more alert, intubation may be averted, but the patient must be diligently observed for deterioration. Increasing respiratory rate, lethargy, exhaustion, speechlessness, paradoxical abdominal breathing movements, and falling oxygen saturation despite therapy mandates invasive ventilation.

The most important factor in the decision to intubate is the patient’s clinical status, not ABG measurements. Even in the face of a significant rise in PaCO₂ with oxygen administration, intubation may be unnecessary if the patient’s clinical status has stabilized. Similarly, improving ABG values should not overrule the clinical impression of deterioration. Temporary improvement may be followed by exhaustion and respiratory failure. Table 72-3 outlines indications for invasive mechanical ventilation. Several of these criteria, adapted from the GOLD collaborators, are subject to interpretation, underscoring...
the critical role of clinical judgment in airway management decisions.

Physicians have an inherent anxiety about using oxygen therapy in patients with COPD because of the fear of inducing apnea by removing the hypoxic drive to breathe. Although controversy surrounds the appropriate use of oxygen in exacerbations of COPD, the risks of hypoxemia need to be weighed against the risk of reducing ventilation. At no time, because of fear of reducing hypoxic ventilatory drive, should a patient be subjected to continued, severe hypoxemia, with its attendant risk of myocardial or tissue ischemia, worsening metabolic acidosis, and muscular fatigue. Despite intervention, including oxygen therapy, intubation is often ultimately required. Although P could rise in response to oxygen therapy, minute ventilation changes little. Thus, titrated oxygen therapy to maintain an oxygen saturation close to 90%, while avoiding an unnecessarily high Fio2, is recommended. This can be done more reliably with the use of Venturi masks than with nasal cannulae. A patient with partial correction of hypoxia, who has mild respiratory acidosis, continues to have a high respiratory drive. It is the patient who is breathing inappropriately slowly who is at highest risk of apnea with oxygen therapy.

In patients who have compensated better, hypoxemia is avoided by hyperventilation. Administering low-flow oxygen by nasal cannulae at 1 to 2 L/minute in such patients raises the Fio2 by a few percent, relieving the sensation of dyspnea. The patient then usually stops hyperventilating, thus reducing the work of breathing and oxygen consumption. This intervention may have significant benefits, especially in the setting of multiple comorbidities, such as myocardial ischemia or sepsis.

**General Drug Therapy**

**Bronchodilators**

Although bronchospasm is not the primary inciting event in acute COPD exacerbation, both beta-agonists and anticholinergic agents are considered first-line agents. The choice of agent for treating a given patient may depend on the respective side effect profiles of these two classes of drugs.

Although many choices are available, inhaled albuterol, which is short-acting with selective beta2-receptor action, is the beta-agonist of choice. The nebulization dose of albuterol is 2.5 to 5.0 mg (0.5–1.0 mL of 0.5% solution). Most patients tolerate two to three rapid successive doses of oxygen-nebulized beta-agonist with little difficulty. Therapy must occasionally be titrated if the side effects of tremor, tachycardia, or ventricular ectopy are significant.

Anticholinergic agents block muscarinic receptors and prevent smooth muscle contraction while decreasing the release of secretions from submucosal glands. Nebulized anticholinergic agents are as effective as beta2-agonists in COPD and can be used alone or in conjunction with beta2-agonists as first-line therapy in acute exacerbations. Although evidence regarding the efficacy of their coadministration is controversial, for moderate to severe exacerbations presenting to the ED, these drugs should be given together for their possible synergistic effects.

**Antibiotics**

In contrast to acute bronchitis in the setting of normal lung function, where antibiotics are clearly of no benefit, some COPD patients with an acute exacerbation appear to benefit from antibiotic therapy. The GOLD collaborators recommend administering antibiotics in patients with an increase in sputum purulence and either increased dyspnea or increased sputum volume, as well as for any patients requiring invasive or noninvasive ventilation (see discussion below on pneumonia). Furthermore, some patients may have clinical pneumonia without radiographic evidence, which may also warrant antibiotic therapy. Since antibiotics are generally benign and potentially beneficial, they should be considered for acute exacerbations in patients presenting to the ED.
Most of the randomized, controlled trials suggesting a treatment benefit with widespread resistance. Amoxicillin, tetracycline, and trimethoprim-sulfamethoxazole were the most common antibiotics used in these studies. Although antibiotics with broader spectrum coverage such as the fluoroquinolones and third-generation cephalosporins are commonly prescribed, the evidence for the superiority of these newer agents is indirect. The GOLD collaborators recommend using antibiotics that reflect local patterns of antibiotic sensitivity to Streptococcus pneumoniae, Haemophilus influenzae, and Moraxella catarrhalis. Azithromycin has the added advantage of once-a-day doses for only 5 days. Ampicillin alone is not recommended because of high rates of resistance.

For outpatient therapy of pneumonia in patients with COPD, an advanced macrolide, such as azithromycin or clarithromycin, can be used in patients who have not recently received antibiotic therapy. In patients who have recently received an antibiotic, a respiratory quinolone, such as levofloxacin, gatifloxacin, or moxifloxacin, can be used or a β-lactam, such as a cephalosporin, can be added to the macrolide. Oral therapy should last for at least 10 days, with longer therapy (2 weeks) if Mycoplasma or Chlamydia pneumoniae are possible causal organisms. For inpatient therapy, no distinction is made for patients with COPD. A more extensive discussion of antibiotic therapy in pneumonia is found in Chapter 74.

### Other Therapeutic Agents

#### Mucokinetic Medications and Mucus Clearance Strategies

Mucus production and cough are cardinal symptoms of COPD. Unfortunately, little objective evidence exists that mucokinetic agents are successful, and they are not recommended. Nebulized saline, oral expectorants, and chest physiotherapy have all failed to demonstrate benefit. Respiratory stimulants have been studied in patients with COPD, including opioid antagonists, progesterone, acetazolamide, doxapram, and almitrine. Doxapram and almitrine appear to be the most effective of these agents. Although doxapram can effect small, temporary improvements in blood gas exchange in the first hours of treatment, it is less effective than other techniques, such as NIVS. Almitrine, which may have a role in chronic therapy, does not have a role in acute respiratory failure. Respiratory stimulants are therefore not recommended for routine use in the ED.

#### Heliox

Helium-oxygen mixtures decrease the work of breathing and improve airflow by virtue of their low density. Such mixtures, however, fail to demonstrate a benefit in either ventilated or nonventilated patients with COPD exacerbations.

### DISPOSITION

Significant deterioration from baseline is the general guideline for admission of patients with COPD. Important factors in the decision include the presence of coexisting conditions, failed outpatient management for the current exacerbation, and lack of improvement while in the ED. The GOLD collaborators propose guidelines for admission, and these are adapted in Table 72-4. If the decision is made to discharge the patient, attention should also be directed to the patient’s vaccination status, proper technique of inhaler use, evaluation of outpatient support systems, appropriate referrals and, perhaps most importantly, smoking cessation.

### Key Concepts

- BNP can be elevated as a result of right ventricular stretch. The clinician may mistakenly assume the cause is left-sided CHF and overlook cor pulmonale or pulmonary embolus.
- Beta-agonists, anticholinergics, and corticosteroids are the mainstay of drug therapy of acute COPD exacerbation.
- Noninvasive ventilatory support (NIVS) is an important therapeutic option in the COPD patient with respiratory failure. It has significant advantages over traditional mechanical ventilation and should be considered when significant dyspnea, acidosis, hypercapnia, and elevated respiratory rate are present.
- Acute complications are common aggravating factors and need consideration during evaluation. These include pneumonia, pneumothorax, and pulmonary embolism.

PHARYNGITIS (TONSILLOPHARYNGITIS)

Perspective and Principles of Disease

Tonsillopharyngitis (from this point on referred to as pharyngitis) is an inflammatory syndrome of the oropharynx. Transmission is mainly through contact with respiratory secretions, but transmission through food and fomite contact is also possible. Although most cases of pharyngitis are uncomplicated and self-limited, the swelling may threaten airway patency or preclude ingestion of adequate liquids, thereby resulting in dehydration.

Etiology

Viruses are responsible for most cases of pharyngitis. Group A beta-hemolytic streptococcus (GABHS) is the most common bacterial cause of pharyngitis in children, with a peak incidence of 30%. Common causes of acute pharyngitis in adults are beta-hemolytic *Streptococcus*, *Mycoplasma pneumoniae*, and *Chlamydia pneumoniae*. Pharyngitis can also be caused by sexually transmitted diseases. Diphtheria is a potentially serious cause of pharyngitis.

Cultures obtained in cases of chronic or recurrent pharyngitis often grow mixed aerobic and anaerobic bacteria. Commonly isolated aerobic organisms include streptococcal species, *Staphylococcus aureus*, *Haemophilus influenzae*, and *Moraxella (Branhamella) catarrhalis*. The anaerobic bacteria most commonly isolated include *Bacteroides*, anaerobic gram-positive cocci, and *Fusobacterium*. β-Lactamase production is extremely common in bacteria responsible for chronic pharyngitis. Epstein-Barr virus (EBV) and *Actinomyces* are also implicated in chronic or recurrent pharyngitis. Rare causes of bacterial pharyngitis include *Francisella tularensis*, *Yersinia pestis*, and *Yersinia enterocolitica*.

Clinical Features

The most common symptom is pharyngeal pain that is aggravated by swallowing and may radiate to the ears. Examination usually reveals fever, pharyngeal erythema, pharyngeal or tonsillar exudate, and tonsillar enlargement (Fig. 73-1). The infection tends to localize to lymphatic tissue and produces suppuration and swelling of the tonsils, along with tender cervical adenopathy. Occlusion of the eustachian tubes may result in secondary otitis media. Clinical differentiation of the etiologic organisms is virtually impossible.

Viral pharyngitis usually occurs in conjunction with cough, rhinorrhea, myalgia, headache, stomatitis, conjunctivitis, exanthem, and odynophagia. Low-grade fever and pharyngeal exudates may be present. Cervical lymphadenopathy is generally absent. Mild pharyngeal edema and erythema associated with a “scratchy” throat are present in 50% of patients with the common cold. Systemic viral infections, including measles, cytomegalovirus (CMV), rubella, and human immunodeficiency virus (HIV), may initially manifest as mild pharyngitis. HIV and CMV pharyngitis may be clinically indistinguishable from infectious mononucleosis.

Influenza occurs in epidemics and is associated with high fever, myalgia, and headache. Although 50 to 80% of patients with influenza experience pharyngeal discomfort, pharyngeal exudate and cervical lymphadenopathy are rare. Adenovirus may cause severe exudative pharyngitis with cervical adenitis similar to that in streptococcal pharyngitis. Thirty percent to 50% of cases of adenoviral pharyngitis are associated with a follicular, usually unilateral, conjunctivitis.

Coxsackieviruses are the most frequent cause of hand-foot-and-mouth disease and herpangina.

Pharyngitis is a common manifestation of infectious mononucleosis (caused by EBV) in young adults. Symptoms develop after an incubation period of 4 to 7 weeks. Fever and a tonsillar exudate or membrane (that is cheesy or creamy white) are often present. Cervical as well as generalized lymphadenopathy (90–100%) and splenomegaly (50%) are usually noted, and palatal petechiae may be present. Hepatomegaly is present in 10 to 15% of cases. Periorbital edema and rash are rare findings. In up to 90% of patients with mononucleosis who are inadvertently given ampicillin or amoxicillin, a diffuse macular rash develops that may be misdiagnosed as an allergic reaction.

Patients with early (days to weeks) HIV infection can develop acute retroviral syndrome. This is manifested by fever, sore throat, generalized nontender lymphadenopathy, a diffuse maculopapular rash, arthralgias, mucocutaneous ulcerations, and, commonly, diarrhea. A nonexudative pharyngitis is present in 50 to 70% of patients. Oral thrush and ulcers may be present. Acute HIV infection can be differentiated from infectious mononucleosis by its more acute presentation, the absence of tonsillar hypertrophy or exudates, the frequent occurrence of rash, and the presence of oral ulcerations.

Herpes simplex also causes pharyngitis. These infections typically affect young adults. The presence of painful vesicles with erythematous bases is characteristic of herpes.
pharyngitis. Ulcers may be present on the pharynx, lips, tongue, gums, and buccal mucosa. Pharyngeal erythema and exudate, fever, and tender lymphadenopathy are common for 1 to 2 weeks. In an immunocompromised host, large painful ulcers may be present. Herpes pharyngitis can be due to primary infection or reactivation. Concomitant bacterial superinfection may occur.1,2

GABHS pharyngitis is primarily a disease of children 5 to 15 years old, and, in temperate climates, occurs in winter and early spring.1,2 It is responsible for less than 15% of cases of pharyngitis in patients older than 15 years and is rare in patients younger than 3 years. In epidemics, the incidence may double.1,2 GABHS pharyngitis is associated with sudden-onset sore throat, fever over 38.3°C (101°F), tonsillar erythema and exudates, palatal and uvular petechiae, uvular edema and erythema, and tender anterior cervical lymphadenopathy. Headache, nausea, vomiting, and abdominal pain may be present, especially in children. Cough, rhinorrhea, coryza, or other viral symptoms are usually absent. GABHS pharyngitis associated with a fine sandpaper erythematous rash that subsequently desquamates is termed scarlet fever. These findings, however, cannot be used to reliably diagnose or exclude streptococcal pharyngitis. Patients with recent exposure to others at risk for GABHS pharyngitis or in whom it has been diagnosed are more likely to become infected.1,3 Non-group A beta-hemolytic streptococcal species can cause pharyngitis indistinguishable from GABHS.1

Diphtheria is a potentially lethal cause of pharyngitis that is uncommon where adequate vaccinations are administered. U.S. serologic surveys indicate that a large percentage of adults and adolescents lack immunity to diphtheria toxin.1 Following a 2- to 4-day incubation period, patients develop malaise, sore throat, fever, and dysphagia. Examination early in the disease process may reveal pharyngeal erythema and isolated spots of gray or white exudate that later coalesce to form a pseudomembrane. This gray-green pseudomembrane is usually well demarcated and covers the nares, tonsils, soft palate, pharyngeal mucosa, and, occasionally, the uvula. The membrane may extend to involve the larynx and tracheobronchial tree, leading to hoarseness, cough, stridor, and airway obstruction. Tender and at times painful cervical lymphadenopathy may be found. Severe inflammation and edema can produce dysphonia and a characteristic “bull neck” appearance. Some strains of Corynebacterium diphtheriae produce a systemic toxin that may cause myocarditis, polyneuritis (at first autonomic and then peripheral), vascular collapse, diffuse focal organ necrosis, and death. Asymptomatic carriers may transmit the disease.1,2 Corynebacterium ulcerans is an animal pathogen passed on by consumption of raw milk that can produce infection indistinguishable from C. diphtheriae.

Aranobacterium haemolyticum (previously called Corynebacterium haemolyticum) typically affects the 10- to 30-year-old age group and can be indistinguishable from streptococcal pharyngitis. Most patients have an associated rash that may be scarlatiniform, urticarial, or erythema multiforme (occasionally skin manifestations may be the only complaint). Patients complain of a moderately severe sore throat and are usually non-toxic and afebrile. A. haemolyticum may cause a membranous pharyngitis that strongly mimics diphtheria; it is also associated with chronic tonsillitis.1,3

Anaerobic pharyngitis, or Vincent’s angina, is characterized by superficial ulceration and necrosis that often results in the formation of a pseudomembrane. Foul-smelling breath, odynophagia, submandibular lymphadenopathy, and exudate are often present. Patients typically have poor oral hygiene.3

Gonococcal pharyngitis is a sexually transmitted disease that may occur independently of genital infection. Those at highest risk are persons who practice receptive oral sex, especially men who have sex with men (in whom the incidence has been reported to be as high as 15%). Its severity is variable and it may result in an exudative or nonexudative pharyngitis. These differing manifestations can be explained in part by the lack of symptoms during the latent period of infection. Asymptomatic carriers are described, as is chronic and recurrent pharyngitis. Gonococcal pharyngitis is an important source of gonococcal meningitis.1,3 Syphilitic pharyngitis is a manifestation of primary or late (tertiary) syphilis and presents with painless mucosal ulcers. Chlamydia trachomatis pharyngitis is a sexually transmitted disease. Similar to gonococcal infection, C. trachomatis pharyngitis is associated with orogenital sex. Urogenital culturing is necessary along with treatment of sexual contacts. Patients are usually asymptomatic or may have only mild symptoms.1,2

Tuberculous pharyngitis usually occurs in patients with advanced disease. Symptoms and signs include hoarseness and dysphagia with pharyngeal ulcerations. Candidal pharyngitis is usually found in immunocompromised adults. Patients have dysphagia, odynophagia, and adherent white plaques with focal bleeding points.

Mycoplasma pneumoniae infection usually causes a mild pharyngitis. Mycoplasma pneumoniae infection occurs in epidemics and in crowded conditions and can be responsible for approximately 10% of cases of adult pharyngitis. Pharyngeal and tonsillar exudates, cervical lymphadenopathy, and hoarseness are common. Lower respiratory tract infection may also be present.1,3

Chlamydia pneumoniae pharyngitis resembles M. pneumoniae pharyngitis. It also occurs in epidemics or crowded conditions. Severe pharyngitis with laryngitis is suggestive of C. pneumoniae infection. Swelling and pain in the deep cervical lymph nodes may be prominent. Lower respiratory tract and concomitant sinusitis occur. The hallmarks of chlamydial pharyngitis are recurrence and persistence.1,2

**Diagnostic Strategies**

Monospot tests may be negative in up to 10% of patients with infectious mononucleosis, especially in the early stages of the illness. Immunoglobulin M (IgM) antibodies to EBV capsid antigen develop in 100% of cases. EBV nuclear antigens develop within 3 to 6 weeks and are useful if an initial negative test becomes positive at a later date. Peripheral blood smears demonstrate atypical mononuclear cells in 75% of patients, with the peak incidence occurring in the second to third week of illness.1,2 Herpes pharyngitis may be diagnosed by culture,
cytopathologic tests on scrapings of lesions, and serologic tests. Enzyme-linked immunosorbent assay testing for HIV can be falsely negative during the first 3 to 4 weeks of illness. During this period of time, quantitative assays for plasma RNA should be performed.1

Diagnosis of GABHS infection is important to prevent complications, particularly rheumatic fever. Even the most experienced practitioner has difficulty clinically diagnosing streptococcal pharyngitis.1,5 Several authors propose scoring systems based on clinical findings,2,8 but the only valid method of determining acute GABHS infection is by acute and convalescent antistreptolysin O titers, which is not practical in the emergency department. A single throat culture has a specificity of 90 to 95% in detecting Streptococcus pyogenes in the pharynx. Variables that affect the accuracy of throat cultures include collection and culturing technique, as well as the recent use of antibiotics.1,3,5

Rapid diagnostic tests for GABHS detect streptococcal antigens. Rapid streptococcal tests (RSTs) have a reported specificity of 70 to 100% (with most being >95%) and a sensitivity of 31 to 100% (with most being 60–95%). Sensitivity and specificity in actual practice are lower than in controlled trials.3 Patients with positive cultures or RSTs may actually be carriers who may not need treatment and are at low risk for transmission and complications. The use of RSTs in patients without clinical findings consistent with GABHS may increase false-positive results. A positive RST seems to reliably indicate the presence of S. pyogenes in the pharynx. In contrast, RSTs are often negative in the setting of pharyngitis with a low bacterial count (these patients are still at risk for complications, including rheumatic fever). It is recommended that a negative RST in a child be followed by a confirmatory culture.1,3,5

Diagnosis and treatment of GABHS in adults is controversial and the subject of two expert panel recommendations.2,3 It is agreed that antibiotics are overused in the treatment of pharyngitis, the use of clinical criteria in conjunction with RSTs improves the accuracy of RSTs, adults with negative RSTs do not require confirmatory cultures (because of the lower incidence of GABHS infection and the extremely low risk for complications), and neither testing nor antibiotic treatment should be used in patients who are clinically at low risk for GABHS infection. Both panels agree that the most useful clinical criteria for determining GABHS pharyngitis are the Centor criteria (Box 73-1).3,5

The position of the Infectious Disease Society of America is that a positive throat culture or RST in addition to clinical symptoms and signs is needed to confirm the diagnosis of GABHS pharyngitis. The society stresses that clinical criteria alone are appropriate to determine which patients do not need testing but are insufficient, without bacterial confirmation, to diagnose GABHS pharyngitis.1

Though controversial, we recommend that: Patients with none or one Centor criterion not be tested or treated. Treat patients with all four criteria without testing. Perform RSTs in patients with two or three criteria, and treat only those who have positive results (Box 73-2).4,5

These recommendations apply only to immunocompetent patients with no underlying comorbid conditions or a history of rheumatic fever. They do not apply in settings of outbreaks of GABHS infection or rheumatic fever, nor are they appropriate in situations in which the endemic rate of rheumatic fever is higher than that in the United States. It is important to consider local epidemics and be prepared to revise the approach to treatment if evidence of GABHS infection or complications exists.3,5 Non–group A streptococcal pharyngitis should also be treated, since the same suppurative complications occur as with group A. Pharyngitis caused by other treatable organisms must also be considered and is associated with serious complications.1,2,4 Confirmation of diphtheria requires culturing on the proper media and immunologic testing (polymerase chain reaction). Toxicogenicity testing must also be performed.1,2 The diagnosis of A. haemolyticum infection should be considered if rash, including erythema multiforme, accompanies pharyngitis. The diagnosis of Vincent’s angina is based on clinical findings and Gram’s stain. In cases of possible gonococcal infection, a sample should be plated on Thayer-Martin agar. Tuberculous pharyngitis is diagnosed by acid-fast staining. Syphilitic pharyngitis is diagnosed with darkfield microscopy, direct immunofluorescence, and serologic testing. Candidal pharyngitis is diagnosed by noting yeast on potassium hydroxide preparations of throat swabs or Sabouraud’s agar.2 The diagnosis of mycoplasmal pharyngitis can be confirmed serologically or by culture. Rapid antigen tests for Mycoplasma are available. Chlamydial pharyngitis can be diagnosed by serologic testing, by culture, or by antigen detection tests. Studies of patients with chronic pharyngitis find that surface cultures do not correlate well with the causal pathogens, which are often concealed within the tonsillar crypts.

**Differential Considerations**

The differential diagnosis of adult pharyngitis includes deep space infections, tumors, foreign bodies, pemphigus, Stevens-Johnson syndrome, drug reactions, allergic reactions, uveitis, angioneuropathic edema, chemical and thermal burns, esophagitis, gastroesophageal reflux disease, cricoarytenoid arthritis, thyroiditis, and epiglottitis.3

**Management**

Patients with pharyngitis should be treated symptomatically with topical anesthetic rinses or lozenges and with acetaminophen or ibuprofen. Oral hydration and saltwater gargles are helpful. Most cases of pharyngitis are self-limited and follow a benign course.1,3–5

Treatment of infectious mononucleosis is supportive (see Chapter 128). Patients should avoid contact sports for 6 to 8 weeks to minimize the small risk of splenic rupture. Corticosteroids are indicated for patients with tonsillar hypertrophy that threatens airway patency, severe thrombocytopenia, or hemolytic anemia.1,2 Acyclovir, valacyclovir, or famciclovir is indicated in immunocompromised patients with herpetic pharyngitis and may be beneficial in the treatment of acute
The use of antiretrovirals is indicated in acute HIV infection.1 Although many studies focus on GABHS pharyngitis, proper treatment of nonstreptococcal pharyngitis can also avoid serious complications. Because clinical judgment is insufficient and rapid diagnostic tests are not always accurate and diagnose only GABHS, this disease process is often treated empirically. The choice of antibiotic for the empirical treatment of adult pharyngitis is not fully elucidated. It is unclear how effective antibiotics are in uncomplicated cases of non-GABHS pharyngitis in adults. Antibiotics may modestly shorten the course of the disease process, but they are also associated with increased recurrence, increased bacterial drug resistance, decreased immune response, and patient expectations for antibiotics with subsequent episodes of pharyngitis.1,3-6

GABHS pharyngitis in children and adolescents must be treated adequately (within 9 days) to prevent rheumatic fever. The incidence of rheumatic fever parallels that of GABHS and has markedly diminished with the use of antibiotics. Patients with mild cases of GABHS pharyngitis may develop rheumatic fever. Current estimates show that rheumatic fever complicates 0.3% of cases of GABHS pharyngitis, but in epidemics the incidence increases to 5%. More troubling is an increase in sporadic outbreaks of rheumatic fever.4,5 The incidence and course of poststreptococcal glomerulonephritis caused by nephritogenic strains are unaffected by antibiotic therapy.1,3-5,8

Antibiotic therapy is extremely effective in eradicating GABHS and its other complications. Untreated, GABHS pharyngitis is a self-limited illness that lasts 3 to 4 days. Early antibiotic treatment of streptococcal pharyngitis leads to a 13% earlier resolution of symptoms and shortens the course of illness by about 1 day. Antibiotic therapy also decreases transmission, and patients are no longer infectious after 24 hours of antibiotic treatment.1,3-6

The antibiotic regimen of choice in adults for GABHS pharyngitis is either a single intramuscular injection of 1.2 million U of benzathine penicillin or a 10-day course of penicillin V, 500 mg orally twice a day. Less frequent dosing is less effective in preventing rheumatic fever.1,3-5 Intramuscular penicillin may be more effective than oral penicillin and ensures compliance, but allergic reactions are more severe as a result of procaine allergy, and treatment is more expensive. Penicillin failure usually reflects noncompliance, reinfection, or the presence of ß-lactamase-producing organisms. Erythromycin is recommended for patients who are allergic to penicillin. A 1-g total daily dose must be given for 10 days, but dosing intervals of two, three, and four times a day are equally effective in preventing rheumatic fever.1,3-5,8 Cephalosporins or clindamycin are also acceptable for penicillin-allergic patients. Once-daily amoxicillin therapy may be effective in children.1,7 Oral cephalosporins may be more effective than penicillin in eradicating GABHS pharyngitis and some authors argue for their use as first-line agents.7 These alternative regimens should be used for patients not responding to penicillin or unable to tolerate either penicillin or erythromycin.1,3-6,7

Patients whose symptoms return within a few weeks of treatment may have been noncompliant with oral therapy or may have acquired a new infection (at times from asymptomatic close contacts). Evaluation and treatment should be similar to that of the first episode, with consideration given to treatment with intramuscular penicillin. Further recurrences mandate more extensive evaluation. Pharyngeal cultures should be obtained and consideration given to evaluating and treating close contacts for GABHS infection.3

Successful treatment of diphtheria is inversely related to the duration of disease. When diphtheria is strongly suspected on the basis of clinical findings, treatment must begin immedi-ately. Airway collapse may occur suddenly and without warning. The mainstay of therapy is antitoxin (a horse serum product), that should be administered immediately on clinical suggestion of diphtheria. The dose of antitoxin varies widely and depends on the site of infection and the duration of symptoms. Antibiotics have little effect on the resolution of systemic toxicity, but they are useful in eradicating C. diphtheriae infection and preventing transmission. Infected patients should remain in strict isolation to prevent transmission. The antibiotic of choice is penicillin G for 5 days, followed by penicillin VK for 5 days, or erythromycin, 500 mg four times a day for 10 days. A small percentage of patients require an additional 10-day course of erythromycin for persistent infection. Rifampin, 600 mg/day for 10 days, is also effective in eradicating the carrier state of C. diphtheriae and treating erythromycin-resistant diphtheria. Diphtheria toxoid should be administered during convalescence and to unvaccinated close contacts.1,2,8

A. haemolyticum may be resistant to penicillin. Erythromycin, 250 mg orally four times a day for 10 days, is the treatment of choice.1,2 Vincent’s angina is treated with penicillin or clindamycin and rinses with an oral oxidizing agent (hydrogen peroxide).8 Gonococcal pharyngitis is often more difficult to eradicate than genital infections. Treatment is similar to that for gonococcal urethritis and consists of ceftriaxone (125 mg intramuscularly) or single-dose oral treatment with either ciprofloxacin (500 mg), ofloxacin (400 mg), or gatifloxacin (400 mg). Concomitant treatment of chlamydial infection with a single oral dose of 1 g of azithromycin or doxycycline, 100 mg orally twice a day for 7 days, is also recommended.5,8 Tuberculous pharyngitis is seen with disseminated disease. Patients should be isolated and treated with a multidrug regimen. Pharyngitis caused by primary syphilis is treated with 2.4 million U of benzathine penicillin (long-acting), with 14 days of tetracycline or doxycycline used as an alternative. Candidal pharyngitis is treated with systemic fluconazole or itraconazole. Alternative therapy includes nystatin (suspension or tablets) or oral clotrimazole for 14 days. Chronic suppression therapy with ketoconazole, clotrimazole, or fluconazole is usually required for HIV pharyngitis.8

M. pneumoniae is treated with erythromycin, tetracycline, or doxycycline for 7 to 14 days.2,8 Chlamydial pharyngitis is treated with doxycycline, trimethoprim-sulfamethoxazole, or a macrolide antibiotic. C. pneumoniae pharyngitis should be treated for 7 to 10 days to prevent treatment failure and recurrence. C. trachomatis pharyngitis may require prolonged or repeated courses of antibiotics.2,8

Treatment of recurrent or chronic tonsillitis should include ß-lactamase-resistant antibiotics active against aerobic and anaerobic organisms. Choices include oral cephalosporins, amoxicillin-clavulanic acid, penicillin with rifampin or metronidazole, or clindamycin.2

Steroids given in conjunction with oral antibiotics in adults with acute pharyngitis may significantly shorten the duration of symptoms and provide a greater degree of pain relief without increasing complications. Oral (40-60 mg of prednisone per day for 1-5 days) or intramuscular (a single dose of 10 mg of dexamethasone) have been found to be equally effective.3,10

Disposition

Although most cases of pharyngitis follow a benign course, life-threatening complications can occur. Airway compromise from tonsillar enlargement, local and distant spread of infection, deep neck abscesses, necrotizing fasciitis, sleep apnea, bacteremia, sepsis, and death are reported.1,3
Infectious mononucleosis may lead to hepatic dysfunction, splenic injury, neurologic disorders, pneumonitis, pericarditis, and hematologic disorders, including thrombocytopenia and hemolytic anemia. Complications of GABHS pharyngitis are both suppurative and non-suppurative. Suppurative complications include peritonsillar abscess, deep space abscesses, suppurative cervical lymphadenitis, otitis media, sinusitis, mastoiditis, bacteremia, sepsis, osteomyelitis, empyema, meningitis, and soft tissue infections. Non-suppurative complications include scarlet fever, rheumatic fever, post-streptococcal glomerulonephritis, non-rheumatic perimyocarditis, erythema nodosum, and streptococcal toxic shock syndrome. In contrast to rheumatic fever, other complications of GABHS pharyngitis are increasing in incidence and severity. A chronic carrier state of streptococcal infection exists and can persist for several months despite treatment. These patients are asymptomatic, at low risk for rheumatic fever, and not considered highly contagious. Non-group A streptococcal pharyngitis may be complicated by the same suppurative complications as group A infections. Scarlet fever and acute glomerulonephritis, but not rheumatic fever, are linked to group C and G pharyngitis.

**LINGUAL TONSILLITIS**

Lingual tonsillitis is a rarely diagnosed cause of pharyngitis that predominantly occurs in patients who have had palatine tonsils removed. The lingual tonsils are a collection of nonencapsulated lymphoid tissue most commonly (size and location are highly variable) located symmetrically on either side of the midline just below the inferior pole of the palatine tonsils and anterior to the vallecula at the base of the tongue. This lymphoid tissue may enlarge after puberty, repeated infection, and tonsillectomy. Patients with lingual tonsillitis have a sore throat that worsens with movement of the tongue (including tongue depression) and phonation. The patient may have a classic “hot potato” voice (the muffled voice one has when eating very hot food) and complain of feeling a swelling in the throat. Dysphagia, fever, respiratory distress, and stridor may be present. Chronic or recurrent lingual tonsillitis may also cause a chronic cough or sleep apnea. Physical findings often include a normal-appearing pharynx with mild hyperemia. Direct or indirect laryngoscopy reveals an edematous lingual tonsil covered with a purulent exudate. Lateral soft tissue neck films aid in the diagnosis. These films demonstrate a normal-appearing epiglottis and arytenoepiglottic folds, with a scalloped appearance on the anterior surface of the vallecula caused by an enlarged lingual tonsil (Fig. 73-2).

Management includes maintenance of airway patency, antibiotics, and supportive therapy. Rarely, acute lingual tonsillitis may be a life-threatening condition. Airway management includes warmed humidified oxygen, hydration, and corticosteroids. Nebulized epinephrine can relieve the acute respiratory distress and stridor. Antibiotics of choice are similar to those used for the treatment of pharyngitis.

**LARYNGITIS**

Laryngitis is manifested as hoarseness and aphony. It is usually caused by viral upper respiratory tract infections. In up to 10% of cases, bacteria (including streptococci and diphtheria) may be responsible. Other infectious causes include tuberculosis, syphilis, leprosy, actinomycosis, and fungal infections. These patients should be evaluated for epiglottitis. Noninfectious causes include tumors, caustic or thermal injuries, trauma, and esophageal reflux disease. Antibiotics are not indicated unless signs of bacterial infection are present. Steroids may hasten resolution of symptoms.

**ADULT EPIGLOTTITIS**

**Perspective**

Adult epiglottitis can lead to rapid, unpredictable airway obstruction. Before the introduction of *H. influenzae* vaccine, epiglottitis was primarily a pediatric disease. Although the incidence of pediatric epiglottitis has diminished, there is an increase in adult epiglottitis. Whether the increase is due to increased recognition or prevalence is unknown.

**Principles of Disease**

Adult epiglottitis is a localized cellulitis involving the supraglottic structures, including the base of the tongue, vallecula, aryepiglottic folds, arytenoid soft tissues, lingual tonsils, and the epiglottis. Inflammation does not extend to the infraglottic regions. Some adults have a normal epiglottis in the setting of severe supraglottic involvement. The term *supraglottitis* is a more accurate description of this disease process. Adults with epiglottic involvement are prone to epiglottic abscesses.

The most commonly isolated bacterial pathogen causing adult epiglottitis is type b *H. influenzae*, but it is only isolated from a minority of affected patients. *H. influenzae* infection is associated with a more aggressive disease course. In many cases, no organisms can be cultured from either blood or the supraglottic structures, which suggests that respiratory viruses may play an important etiologic role. The predominant organisms isolated from epiglottic abscesses are *Streptococcus* and *Staphylococcus* species. Adult epiglottitis may also result from thermal injury.

**Clinical Features**

Adult epiglottitis has no age or seasonal prevalence. Males and smokers are more commonly affected. Adults with epiglottitis typically experience a prodrome resembling that of a benign upper respiratory tract infection. The duration of the prodrome is usually 1 to 2 days but may be as long as 7 days or as short as several hours. Patients who have a rapid onset of the disease as well as those with comorbid conditions (especially diabetics) are more likely to require airway intervention.

Patients typically have dysphagia, odynophagia, and a sore throat. Pharyngeal pain may be severe and is often disproportionate to the clinical findings. Dysphonia and a muffled voice...
are common, while hoarseness is unusual. Fever is absent in up to 50% of cases and may develop only in the later stages of the disease. Tachycardia disproportionate to fever correlates with severe disease. Tenderness to palpation of the anterior aspect of the neck in the region of the hyoid and when moving the larynx side to side is a reliable finding in epiglottitis. Ear pain may be a manifestation of adult epiglottitis.

Concomitant uvulitis, pharyngitis, tonsillitis, Ludwig’s angina, peritonsillar abscess, and parotitis can occur; therefore, these findings on pharyngeal examination do not exclude the diagnosis of epiglottitis. The classic symptoms and signs of imminent airway obstruction may not appear until immediately before complete obstruction occurs, thus the earlier signs of drooling and dysphonia are more compelling indicators of impending airway compromise. Patients who assume a classic sniffing position are at imminent risk for rapid airway obstruction. These patients should not be laid flat, and immediate preparations must be made to rapidly secure the airway (see Chapter 1).

Diagnostic Strategies

Although severe cases of adult epiglottitis are easily recognized, a large number of less severe cases are initially misdiagnosed. In up to a third of adult patients, epiglottitis is present but not diagnosed within 48 hours of admission.

Adult patients without respiratory distress should undergo fiberoptic or rigid direct laryngoscopy, or indirect laryngoscopy, but preparations should include the ability to provide immediate bag-mask ventilation, intubation, or cricothyrotomy. Laryngospasm and complete obstruction can occur during instrumentation of the inflamed airway. Flexible fiberoptic laryngoscopy is the preferred approach as it provides direct, minimally invasive examination of the upper airway and can be used to determine the need for, and imminence of, airway management. Laryngoscopy reveals a swollen epiglottis and surrounding structures (Fig. 73-3). The epiglottis may appear “cherry red” but is often pale and edematous. In patients with respiratory distress, drooling, aphony, or stridor, indirect laryngoscopy is contraindicated and direct laryngoscopy should be undertaken only as part of a “double setup” with the ability to proceed immediately to cricothyrotomy.

Lateral cervical soft tissue radiographic films have a sensitivity of up to 90% compared with direct laryngoscopy; however, normal soft tissue plain films do not exclude mild or moderate adult epiglottitis. Adults with possible epiglottitis and normal soft tissue radiographic films should undergo laryngoscopy as described earlier. Radiologic findings include obliteration of the vallecula, swelling of the arytenoids and aryepiglottic folds, edema of the prevertebral and retropharyngeal soft tissues, and “ballooning” of the hypopharynx and mesopharynx. The edematous epiglottis appears enlarged and thumb-shaped (Fig. 73-4). An epiglottic width greater than 8 mm or an aryepiglottic fold width greater than 7 mm is suggestive of epiglottitis.

Differential Considerations

Adult epiglottitis is often misdiagnosed as streptococcal pharyngitis. Other entities that must be considered include mononucleosis, deep space abscesses, lingual tonsillitis, diphtheria, pertussis, and croup. Noninfectious considerations include angioedema, allergic reactions, foreign body aspiration, laryngospasm, tumors, toxic inhalation or aspiration, and laryngeal trauma.

Management

Most adults with epiglottitis do not require intubation, but all patients with epiglottitis should be treated with extreme care because of the possibility of unpredictable sudden airway obstruction. Endotracheal intubation should always be performed under direct visualization. Awake fiberoptic intubation is the optimal method, but awake orotracheal intubation by direct laryngoscopy is also safe and effective. Blind nasotracheal intubation can lead to airway obstruction and is contraindicated in the setting of epiglottitis.
Antibiotics should be initiated against *H. influenzae* and other likely bacterial pathogens. First-line agents pending culture and sensitivity results are cefotaxime and ceftriaxone. Alternative antibiotics include ampicillin-sulbactam and trimethoprimsulfamethoxazole.1,8,9 The role of steroids and racemic epinephrine is unresolved.

**Disposition**

Stable patients, particularly those who present more than 24 hours after onset of symptoms, who are without respiratory distress, and who are handling their secretions can be safely observed without intubation in the emergency department observation unit or a higher level inpatient unit (intermediate or intensive care unit). Such patients include those with mild swelling on laryngoscopy and without drooling, stridor, or dyspnea. Patients who have a rapidly progressive course, are immunocompromised or diabetic, or have an epiglottic abscess or significant epiglottic enlargement on plain film study or laryngoscopy are at high risk.1,16,17

Extraepiglottic infections are less likely to occur in adults than children. Meningitis, retropharyngeal abscess, pneumomediastinum, empyema, pneumonia, sepsis, acute respiratory distress syndrome, necrotizing fasciitis, mediastinitis, and pulmonary edema occur in conjunction with epiglottitis.

### DEEP SPACE INFECTIONS OF THE LOWER PART OF THE FACE AND NECK

Patients with deep space infections of the head and neck (Fig. 73-5) can decompensate rapidly. The incidence and complications of deep space infections have decreased dramatically because of improved dental hygiene and the advent of antibiotics.18

The submandibular space comprises two spaces: the sublingual and submaxillary spaces. The submandibular space is involved in Ludwig’s angina.19 Five potential communicating spaces in the neck are clinically relevant: the peritonsillar, parapharyngeal, retropharyngeal, “danger,” and prevertebral spaces. The parapharyngeal space contains the carotid artery, the jugular vein, the cervical sympathetic chain, and cranial nerves IX through XII. The retropharyngeal space lies in the midline (medial to the parapharyngeal space) and extends from the base of the skull to the superior mediastinum (at about the level of T2). Retropharyngeal abscesses tend to occur lateral to the midline. Posterior to the retropharyngeal space lies the “danger space,” which extends from the base of the skull to the diaphragm. The prevertebral space extends from the base of the skull to the coccyx. Danger space and prevertebral abscesses are located in the midline. Infections in the retropharyngeal, danger, and prevertebral spaces easily access the mediastinum.18,20

The primary pathologic process of deep space infection is regional cellulitis. The fasciae may confine infections within their boundaries, thereby leading to abscess formation. Infections are most commonly a polymicrobial disease of mixed aerobic-anaerobic bacteria of oral origin. The most frequently isolated organisms are streptococci, staphylococci, and *Bacteroides* species. β-Lactamase-producing organisms are isolated in up to two thirds of cases. Other organisms include *H. influenzae*, *Pseudomonas aeruginosa*, Klebsiella species, and *Candida albicans*.18,19,21

Computed tomography (CT) and magnetic resonance imaging (MRI) can help distinguish cellulitis from abscess formation and guide therapy. Patients with cellulitis usually respond well to high-dose antibiotic therapy. Patients with small abscesses may be successfully treated with high-dose intravenous antibiotics or needle aspiration. The presence of an abscess, however, usually requires surgical incision and drainage. With the exception of patients with uncomplicated peritonsillar abscesses, patients with deep space abscess usually require admission, intravenous (IV) antibiotics, and consultation with otolaryngologists for possible surgical intervention.22

There is little anatomic resistance to spread of infection within the fascial planes and spaces, which allows rapid spread of infection. Life-threatening complications can occur rapidly.

Airway distortion and trismus may complicate intubation attempts. Neuromuscular blockade is generally ill-advised, unless as part of a “double setup” with the ability to proceed directly to cricothyrotomy, because both intubation and bag-mask ventilation may be impossible. Awake techniques are preferable. Fiberoptic-guided intubation can be useful in this setting.18,19,22 Blind nasotracheal intubation can cause abcess rupture and further compromise and is thus contraindicated.19,23

Should it be necessary to secure an airway surgically, cricothyroidotomy is generally the procedure of choice, except in some cases of Ludwig’s angina, in which anatomic distortion may necessitate tracheostomy.

#### PERITONSILLITIS (PERITONSILLAR CELLULITIS AND PERITONSILLAR ABSCESS)

**Perspective**

Peritonsillar cellulitis and abscess should be regarded as the clinical continuum of peritonsillitis. Peritonsillar abscess, also termed quinsy, is the most common deep infection of the head and neck in adults.

**Principles of Disease**

Peritonsillitis may occur as a result of acute tonsillitis. Infection in either Weber’s glands or the tonsillar crypts invades the peritonsillar tissues and thereby leads to cellulitis and abscess formation. Fibrous fascial septa divide the peritonsillar space into compartments and direct the infection anteriorly and superiorly.1,18

![Figure 73-5. Lateral view of the neck showing the relationship of fascia to the prevertebral, “danger,” retropharyngeal, and submandibular space.](image-url)
Dental infections, chronic tonsillitis, infectious mononucleosis, smoking, chronic lymphocytic leukemia, and tonsilloliths are predisposing factors. Peritonsillar abscess occurs in patients who have undergone complete tonsillectomy and is seen in all age groups. Peritonsillitis recurs in up to 50% of patients, with the incidence of recurrent peritonsillar abscess of approximately 10%. The highest incidence of recurrence is seen in patients younger than 40 years and in those with a history of chronic tonsillitis.

Most peritonsillar abscesses are polymicrobial. In patients who have received antibiotics in whom peritonsillar abscesses develop, fewer aerobes and more β-lactamase-producing organisms are isolated.\(^1\)\(^,\)\(^18\)

**Clinical Features**

There is often a delay of 2 to 5 days between abscess formation and local and systemic symptoms. Symptoms and signs include odynophagia, dysphagia, drooling, trismus, and referred otalgia. Patients may have a characteristic muffled, hot potato voice and rancid breath. Systemic manifestations include fever, malaise, and dehydration. Patients often relate a history of recurrent tonsillitis with multiple trials of antibiotics but without resolution.

The examination of the pharynx may be limited by trismus. Physical findings of peritonsillitis include inflamed and erythematous oral mucosa, purulent tonsillar exudates that obscure the tonsil, and tender cervical lymphadenopathy. Peritonsillar cellulitis mimics peritonsillar abscess. Peritonsillar abscess is characterized by a greater frequency of drooling, trismus, and dysphagia, whereas peritonsillar cellulitis is more commonly bilateral. The distinguishing feature of peritonsillar abscess is inferior medial displacement of the infected tonsil (at times involving the soft palate), with contralateral deviation of the uvula (Fig. 73-6). The abscess is generally unilateral and located in the superior pole of the tonsil. Bilateral peritonsillar abscesses occur occasionally.\(^1\)\(^,\)\(^18\)

**Diagnostic Strategies**

Aspiration of pus establishes the diagnosis of peritonsillar abscess. Because patients with peritonsillar abscess have a 20% incidence of mononucleosis, laboratory testing for mononucleosis should be considered.

Roentgenographic examination in uncomplicated cases contributes little to the diagnosis. Contrast-enhanced CT and ultrasonography (both intraoral and transcutaneous) aid in differentiating peritonsillar abscess from cellulitis, especially when patients are unable to cooperate with needle aspiration. These modalities are also useful in diagnosing posteriorly and inferiorly located abscesses and in guiding needle aspiration.\(^18\)\(^,\)\(^22\)\(^,\)\(^24\)

**Differential Considerations**

The differential diagnosis of peritonsillitis includes hypertrophic tonsillitis, infectious mononucleosis, tuberculous granuloma, diphtheria, other deep space infections of the neck, cervical adenitis, congenital or traumatic internal carotid artery aneurysms, foreign bodies, and neoplasms.

**Management**

Emergency abscess aspiration is necessary in cases of complete or impending airway obstruction. Antibiotics alone may control peritonsillar cellulitis. Regimens include high-dose penicillin plus metronidazole, cefoxitin, ampicillin-sulbactam, and clindamycin. Alternative antimicrobial agents include a carbapenem, high-dose penicillin and rifampin, ticarcillin-clavulanate, or piperacillin-tazobactam.\(^1\)\(^,\)\(^8\)\(^,\)\(^18\) β-Lactamase-producing bacteria and poor penetration of antibiotics into the abscess limit the effectiveness of antibiotics. The use of steroids may be beneficial.\(^25\)

Drainage of the abscess is curative. Needle aspiration of abscesses by both emergency physicians and otolaryngologists is diagnostic (although false-negative aspirations occur in approximately 10% of cases, and another 10% may require repeated aspirations) and therapeutic. This immediately relieves symptoms and is more cost-effective, less painful, and easier to perform than incision and drainage.\(^1\)\(^,\)\(^8\)\(^,\)\(^18\)\(^,\)\(^22\)\(^,\)\(^24\) Intraoral ultrasound-guided needle aspiration is a useful adjunct in the presence of trismus.\(^24\)\(^,\)\(^25\) Immediate tonsillectomy under general anesthesia may be needed in extremely young or uncooperative patients.

**Disposition**

Hospital admission is indicated for patients who have underlying disease, are dehydrated, appear toxic, are unable to tolerate oral fluids, are in severe pain, or have other significant complications. The most dangerous immediate complication of peritonsillitis is pharyngeal obstruction with upper airway compromise. Other complications include sepsis, abscess rupture and pulmonary aspiration leading to pneumonia, empyema, and pulmonary abscess formation. Infection can spread contiguously to the parapharyngeal and retropharyngeal spaces. Ludwig’s angina, mediastinal involvement (including mediastinitis, pneumonia, empyema, and pericarditis), myocarditis, carotid artery erosion, jugular vein thrombophlebitis, septic embolization, abscess formation, Lemierre’s syndrome (postanginal septicemia), and cervicopharyngeal necrotizing fasciitis can complicate peritonsillitis. Intracranial extension of peritonsillitis may result in meningitis, cavernous sinus thrombosis, and cerebral abscess.\(^18\)

**LUDWIG’S ANGINA**

**Perspective and Principles of Disease**

Ludwig’s angina is a potentially fulminant disease process that can lead to death within hours.\(^1\)\(^9\)\(^,\)\(^21\)\(^,\)\(^26\) This is a progressive cellulitis of the connective tissues of the floor of the mouth and neck that begins in the submandibular space. Dental disease is the most common cause of Ludwig’s angina. An infected or recently extracted lower molar is noted in most affected
patients. Dentoalveolar abscesses easily break through the relatively thin cortex of the mandible below the mylohyoid ridge and infect the submandibular space. Other causes of Ludwig’s angina include a fractured mandible, foreign body or laceration in the floor of the mouth, tongue piercing, traumatic intubation and bronchoscopy, secondary infections of an oral malignancy, osteomyelitis, otitis media, submandibular sialadenitis, peritonsillar abscess, a furuncle, infected thyroglossal cyst, and sepsis.

Clinical Features

Infection of the sublingual and submaxillary spaces leads to edema and soft tissue displacement, which may result in airway obstruction. The most common presentation in patients with Ludwig’s angina includes dysphagia, odynophagia, neck swelling, and neck pain. Other symptoms and signs include dysphonia, a hot potato voice, dysarthria, drooling, tongue swelling, pain in the floor of the mouth, restricted neck movement, and sore throat. Patients should be questioned regarding recent dental extraction and disease. A foul taste in the patient’s mouth, feeling air release at the time of extraction, rapid development of crepitus, and unilateral pharyngitis in patients with recent dental extractions should suggest the diagnosis of Ludwig’s angina.

The most common physical findings in Ludwig’s angina are bilateral submandibular swelling and elevation or protrusion of the tongue. Other findings include elevation of the floor of the mouth, posterior displacement of the tongue, and a “woody” consistency of the floor of the mouth. The combination of tense edema and brawny induration of the neck above the hyoid may be present and is described as a “bull neck.” Marked tenderness to palpation of the neck and subcutaneous emphysema may be noted. Trismus and fever are usually present, but generally no palpable fluctuance or cervical lymphadenopathy. Tenderness to percussion may be elicited over the involved teeth.

Diagnostic Strategies

The diagnosis is made clinically by examination. Soft tissue plain films of the neck may confirm the diagnosis by showing swelling of the affected area and airway narrowing and by identifying gas collections. CT and MRI aid in the diagnosis of Ludwig’s angina and its complications. Ultrasonography is also useful in diagnosing abscesses and edema in the setting of Ludwig’s angina.

Differential Considerations

The differential diagnosis includes deep cervical node suppuration, peritonsillar and other deep neck space abscess, parotid and submandibular gland abscess, oral carcinoma, angioedema, submandibular hematoma, and laryngeal diphtheria.

Management

Sudden asphyxiation is the most common cause of death in patients with Ludwig’s angina. Stridor, tachypnea, dyspnea, inability to handle secretions, and agitation are all indications of impending airway compromise. Fiberoptic-guided oral or nasotracheal intubation under sedation with topical anesthesia is the preferred method of airway control. Endotracheal intubation may be difficult because of distortion of the upper airway, trismus, pooled secretions, the cephalad and posterior displacement of the tongue, inability to displace the tongue into the submandibular space, and a tendency for the development of laryngospasm. Cricothyotomy may be difficult and opens tissue planes that increase the risk of spreading infection into the mediastinum, but is the procedure of choice if fiberoptic intubation is not available.

Emergent antibiotic regimens are similar to those for peritonsillar abscess. The value of corticosteroids in the setting of Ludwig’s angina is unclear. With the exception of dental extractions, surgery is reserved for patients who do not respond to medical therapy and those with crepitus and purulent collections.

Disposition

The mortality rate resulting from Ludwig’s angina is less than 10% with early aggressive antibiotic therapy and adequate protection of the airway. Infection can easily spread into other deep spaces of the neck and into the thoracic cavity and cause empyema, mediastinitis, mediastinal abscess, and pericarditis. Aspiration may lead to pneumonia and the formation of lung abscesses. Other complications include internal jugular vein thrombosis, carotid artery infection and erosion, bacteremia and sepsis, pneumoperitoneum, subphrenic abscess, cervicothoracic necrotizing fasciitis, and spontaneous pneumothorax.

Retropharyngeal Abscess

Perspective and Principles of Disease

Retropharyngeal swelling reflects expansion of the retropharyngeal, danger, or prevertebral spaces. This discussion refers to infections in these spaces collectively as retropharyngeal abscesses.

Retropharyngeal abscess was previously a disease of childhood, with 96% of cases occurring in patients younger than 6 years. Adults are now increasingly affected. Children younger than 4 years have prominent retropharyngeal lymph nodes that may become infected and lead to retropharyngeal cellulitis and abscess formation. The increased use of antibiotics to treat pharyngitis in children has led to a declining incidence of retropharyngeal abscesses in this age group. These retropharyngeal nodes atrophy after 4 to 6 years of age, and thus the incidence and pathophysiology of this entity differ in adults.

In adult patients, cellulitis develops in the retropharyngeal area. Once the retropharyngeal space is involved, the infection spreads rapidly and an abscess may form. Nasopharyngitis, otitis media, parotitis, tonsillitis, peritonsillar abscess, dental infections and procedures, upper airway instrumentation, endoscopy, lateral pharyngeal space infection, and Ludwig’s angina are all implicated in the development of retropharyngeal abscesses. Other causes include blunt and penetrating trauma (usually from foreign bodies, commonly fish bones), ingestion of caustic substances, vertebral fractures, and hematologic spread from distant infection. Vertebral osteomyelitis and diskitis may lead to infection of the prevertebral space. Danger space infections are caused by extension of infection from either the retropharyngeal or prevertebral spaces. Underlying systemic disorders (e.g., diabetes and depressed immune system) may predispose individuals to retropharyngeal infections.

Retropharyngeal abscesses are most commonly polymicrobial with a mixture of aerobes and anaerobes. β-Lactamase-producing organisms are present in two thirds of the cases. Tuberculosis is rarely reported in the United States as a cause of retropharyngeal abscess. Staphylococcus is currently the most common cause of pyogenic vertebral osteomyelitis.
leading to the formation of retropharyngeal abscess. Disseminated coccidioidomycosis may also cause retropharyngeal abscess.18,22,27,28

**Clinical Features**

Patients typically have a sore throat, dysphagia, odynophagia, drooling, a muffled voice, neck stiffness, neck pain, and fever. Dysphonia is usually present and is described as a duck “quack” (cri du canard). Patients may complain of feeling a lump in their throat. Patients with a retropharyngeal abscess may appear quite ill and generally prefer to hold their necks extended and remain in the supine position. This position keeps the swollen posterior pharynx from compressing the upper airway. Forcing the patient to sit may lead to increased dyspnea.18,26

Physical examination may reveal tender cervical lymphadenopathy, tender cervical musculature, neck swelling, torticollis, and often a high fever. Trismus may be present and make visualization of the pharynx difficult. In cases of retropharyngeal cellulitis, diffuse edema and erythema of the posterior pharynx are present.18,26 Once an abscess develops, palpation of the pharynx may demonstrate a unilateral mass if the retropharyngeal space is affected and a midline mass if the abscess is in the prevertebral or danger space. Palpation of a fluctuant mass is unreliable and carries a risk of inadvertent rupture of the abscess. Tenderness on moving the larynx and trachea side to side (tracheal “rock” sign) is commonly present. A retropharyngeal abscess may also cause pain in the back of the neck or shoulder that is precipitated by swallowing. Cold abscesses (caused by tuberculosis) are characterized by insidious onset, chronicity, constitutional symptoms, and less of a febrile response. Symptoms disproportionate to the findings should prompt further evaluation.28

**Diagnostic Strategies**

Diagnosis rests on the clinical findings and lateral cervical radiographs, CT, and MRI (Fig. 73-7). The soft tissue along the anterior bodies of C1-C4 should be less than 40% of the diameter of the vertebral body just behind it; an increase in this tissue thickness suggests infection or abscess. Inspiratory lateral neck films often demonstrate thickening of the retropharyngeal soft tissues with forward displacement of the larynx and esophagus.20 The soft tissue swelling may be diffuse in the case of cellulitis or more focal if an abscess cavity is present. A pathologic process is suggested if the retropharyngeal space on lateral neck films (measured from the anteroinferior aspect of the second vertebral body to the posterior pharyngeal wall) is wider than 7 mm in both children and adults or the retrotracheal space (measured from the anteroinferior aspect of the sixth vertebral body to the posterior pharyngeal wall) is more than 14 mm in children and 22 mm in adults. True lateral films with the neck fully extended during deep inspiration are the most reliable. Other radiographic findings include reversal of the normal lordosis of the cervical spine, air-fluid levels in the abscess cavity, foreign bodies, and vertebral body destruction.

Plain films may not be sufficiently sensitive to diagnose retropharyngeal abscess. CT or MRI should be performed in these instances. These studies not only aid in the diagnosis and differentiation between cellulitis and abscess but also determine the extent of the disease process and the presence of complications (Fig. 73-8).20,22,28 Ultrasonography is useful for differentiating retropharyngeal cellulitis from retropharyngeal abscess.

**Differential Considerations**

The differential diagnosis includes retropharyngeal tumors, foreign bodies, inflammation, hematoma, aneurysms, hemorrhage, lymphadenopathy, and edema. Other considerations...
include tendinitis of the longus colli muscle and retropharyngeal thyroid tissue.\textsuperscript{20}

Management

Patients with retropharyngeal cellulitis are best treated with high-dose IV antibiotics. Appropriate regimens are similar to those used for peritonsillar abscess. Tuberculosis and fungal infections must also be considered. Resolution of retropharyngeal cellulitis is possible without surgical intervention.\textsuperscript{8,18,22,26,28}

Generally, retropharyngeal abscesses are treated with antibiotics, in conjunction with operative incision and drainage. In selected cases, retropharyngeal abscesses can be treated successfully with antibiotics alone or in combination with needle aspiration. Cold abscesses should only be drained extraorally, unless the patient is in acute respiratory distress.\textsuperscript{22,26,28}

Neck immobilization may be necessary in patients with vertebral body destruction caused by osteomyelitis or atlantoaxial separation. These patients need neurosurgical or orthopedic evaluation and may require internal or external fixation.

Disposition

Airway compromise can be caused by anterior displacement of the pharyngeal tissues. Pulmonary complications include abscess rupture with aspiration and subsequent pneumonia, empyema, and asphyxiation. Extension of the infection along tissue planes and through other deep spaces may lead to mediastinitis and mediastinal abscess formation, pericarditis, pleuritis, and empyema. In addition, abscesses may track into the back of the neck and into the axilla. Vascular complications occur from the extension of the retropharyngeal abscess into the lateral pharyngeal space. Atraumatic atlantoaxial separation is due to damage to the transverse ligament of the atlas by the abscess. These patients may have neurologic symptoms and a widened predental space on plain films, CT scan, or MRI. Acute transverse myelitis and epidural abscesses also occur, and both can result in quadriplegia. Other complications include internal carotid pseudoaneurysm, erosion into the esophagus and auditory canal, necrotizing fasciitis of the neck, acute respiratory distress syndrome, sepsis, and death.\textsuperscript{18,28}

PARAPHARYNGEAL ABSCESS

Perspective

The parapharyngeal space, also known as the lateral pharyngeal and pharyngomaxillary space, is divided into two compartments by the styloid process. The anterior compartment contains connective tissue, muscle, and lymph nodes. The carotid sheath (which contains the carotid artery, internal jugular vein, vagus nerve, cranial nerves IX through XII, and the cervical sympathetic chain) runs in the posterior compartment.\textsuperscript{18}

Principles of Disease

Parapharyngeal abscesses are most often polymicrobial infections. Odontogenic and pharyngotonsillar infections are the most common causes of parapharyngeal space abscesses. Parapharyngeal space infections can also arise by contiguous spread from other surrounding deep neck space infections. Other causes include parotitis, sinusitis, spread from infected neck tumors, infected branchial cleft cysts, suppurative of local lymphadenitis, iatrogenic introduction of organisms during a mandibular nerve block or anesthesia for tonsillectomy, nasal intubation, dental extraction, chronic otitis with cholesteatoma, and mastoiditis.\textsuperscript{18}

Clinical Findings

Pain and swelling of the neck are the most common complaints. Odynophagia is present in most patients. A history of an antecedent sore throat may be elicited in some patients. Torticollis caused by irritation of the sternocleidomastoid muscle is also reported.\textsuperscript{18}

The classic physical findings of infection involving the anterior compartment of the parapharyngeal space are medial tonsillar displacement and posterolateral pharyngeal wall bulging. Other findings include fever, trismus (caused by irritation of the muscles of mastication), edema, and swelling at the angle of the jaw. An erythematous, tender, nonfluctuant swelling at the angle of the mandible is a consistent finding in patients with an anterior parapharyngeal abscess.\textsuperscript{18}

Involvement of the posterior space is associated with many of these same signs. If the anterior compartment is spared, however, little or no trismus occurs. Instead, posterior displacement of the tonsillar pillar and retropharyngeal swelling may be present.\textsuperscript{18}

Diagnostic Strategies and Differential Considerations

The diagnosis of parapharyngeal abscess is suggested by the presence of a severe sore throat with the characteristic physical findings. Blood cultures are usually sterile unless jugular vein thrombophlebitis is complicating the parapharyngeal space infection. Ultrasonography, CT, and MRI are more useful than lateral radiographs in diagnosing parapharyngeal abscesses and its complications. Angiography, Doppler flow studies, and magnetic resonance angiography may also be helpful in evaluating vascular complications.\textsuperscript{18,22,29}

The differential diagnosis includes infections in other deep spaces of the neck, tumors and metastatic lymph nodes, thyroiditis, branchial cleft cyst, and carotid artery aneurysms.

Management

Treatment includes high-dose IV antibiotics and consultation with an otolaryngologist for surgical drainage of the abscess cavity. Appropriate antibiotic regimens are discussed in the section on the treatment of peritonsillar abscess. Intravenous antibiotics alone will cure parapharyngeal space infections in selected patients and should be started on an emergency basis.\textsuperscript{8,18,22,29,30} Successful resolution of parapharyngeal abscesses with high-dose IV antibiotics and needle aspiration is reported.\textsuperscript{22,29}

Disposition

Complications of a parapharyngeal abscess include airway obstruction and abscess rupture with subsequent aspiration, pneumonia, and empyema. Infection can spread to surrounding spaces and into the mediastinum and pericardium. Such spread may lead to mediastinitis, mediastinal abscess, pericarditis, myocardial abscess, and empyema. Other complications include osteomyelitis of the mandible, cervicothoracic necrotizing fasciitis, parotid abscess, cavernous sinus thrombosis, and meningitis.\textsuperscript{16}

Posterior parapharyngeal space infections are particularly dangerous. These infections may affect the cervical sympathetic chain, carotid artery, or internal jugular vein. Ipsilateral
Horner’s syndrome and neuropathies of cranial nerves IX through XII may occur. Carotid artery erosion may lead to hemorrhage and the formation of aneurysms. Oral, nasal, and aural warning bleeding is common with carotid artery erosion, with aural bleeding being particularly ominous. Any unexplained bleeding associated with parapharyngeal or other deep neck space infection should be investigated thoroughly. Persistent peritonsillar swelling despite resolution of the parapharyngeal abscess or a tender unilateral pulsatile mass may indicate an arterial aneurysm. Aspiration or incision of a carotid artery aneurysm thought to be a parapharyngeal abscess may have disastrous complications.  

Involvement of the internal jugular vein may lead to septic thrombosis and Lemierre’s syndrome. This entity, also called postanginal septicemia, affects primarily young healthy patients and is easily confused with right-sided endocarditis or aspiration pneumonia. The manifestation is one of a pharyngitis that initially improves but is then followed by severe sepsis. It is thought that the pharyngeal infection spreads to the parapharyngeal space and causes septic thrombophlebitis of the jugular vein. Patients usually appear ill and are febrile. Metastatic infections involve primarily the lung and are manifested by bilateral nodular infiltrates, pleural effusion, and pneumothorax. Septic arthritis, osteomyelitis, soft tissue cellulitis and abscesses, meningitis, and a vesiculopustular rash are also reported as a result of septic embolization. Leukocytosis and elevated bilirubin and liver function test values, with and without hepatomegaly and jaundice, are often present. Albuminuria, hematuria, and elevations in serum creatinine and blood urea nitrogen are reported. Septic shock rarely develops, although acute respiratory distress syndrome, transient coagulopathies, and hypotension commonly occur. The most frequent cause of this entity is *Fusobacterium* (primarily *Fusobacterium necrophorum*), although *S. aureus* is the most common pathogen in IV drug users. Treatment consists of parenteral antibiotics and incision and drainage of abscesses. Jugular vein ligation and resection are necessary in patients with uncontrolled sepsis and respiratory failure caused by repeated septic pulmonary emboli. The value of anticoagulation is unknown.

### RHINOSINUSITIS

#### Perspective and Principles of Disease

It is estimated that 0.5 to 2% of viral upper respiratory tract infections are complicated by rhinosinusitis. Since sinusitis usually involves the nasal cavity, the term rhinosinusitis is preferred. These terms will be used interchangeably in this section.  

The paranasal sinuses (frontal, maxillary, ethmoid, and sphenoid) are named for the facial bones with which they are associated. Pneumatization may involve other bones but represents extension from the main sinus. The maxillary, anterior ethmoid, and frontal sinuses drain into the medial meatus, located between the inferior and middle nasal turbinates. This area is named the ostiomeatal complex and is the focal point of sinus disease. The posterior ethmoid sinus drains into the superior meatus and the sphenoid sinus just above the superior turbinate.  

A healthy sinus depends on a patent ostium with free air exchange and mucus drainage. A healthy sinus is sterile and does not accumulate mucus. Viral upper respiratory tract infections and allergic rhinitis are the most common causes of ostial obstruction with resultant sinusitis. Ciliary abnormality or immobility inhibits drainage and is another important cause of sinusitis. Ciliary dysfunction can be temporary (e.g., upper respiratory infection) or permanent (e.g., syndromes associated with ciliary structural abnormalities). Infection leads to increased mucus viscosity, thus further impeding drainage. Bacteria are introduced into the sinus by coughing and nose blowing. These processes lead to increased inflammation and bacterial overgrowth. Other factors predisposing to rhinosinusitis include immunocompromised status, nasal septal deviation and other structural abnormalities, nasal polyps, nasal tumors, trauma and fractures, rhinitis medicamentosa, rhinitis secondary to toxic mucosal exposure, barotrauma, foreign bodies, nasal cocaine abuse, and instrumentation (including nasogastric and nasotracheal intubation).  

Sinusitis can be classified into acute viral, acute bacterial, chronic, and recurrent acute variations. Approximately 90% of patients with colds have an element of the acute viral form. Acute viral sinusitis may lead to the development of the acute bacterial variety, *S. pneumoniae*, nontypable *H. influenzae*, and *M. catarrhalis* are the primary pathogens responsible for acute bacterial and recurrent acute sinusitis. *P. aeruginosa* is associated with sinusitis in the setting of HIV infection and cystic fibrosis. Anaerobic bacteria, streptococcal species, and *S. aureus* are more prominent causes of chronic sinusitis. Fungi also have a role in CS. *Rhizopus, Aspergillus, Candida, Histoplasma, Blastomyces, Coccidioides*, and *Cryptococcus* species, as well as other fungi, may cause sinusitis, primarily in immunocompromised hosts. It is important to distinguish infectious from allergic sinusitis. Allergic sinusitis is associated with sneezing, itchy eyes, allergen exposure, and previous episodes.  

#### Clinical Features

Frontal sinusitis can cause severe headache localized to the forehead and orbit. Sphenoid sinusitis may cause vague headaches and focal pain almost anywhere in the head. Maxillary sinusitis may be seen with pain over the zygoma, in the canine or bicuspid teeth, or periorbitally. Ethmoid sinusitis can cause medial canthal pain and periorbital or temporal headaches.  

The cardinal symptoms of acute rhinosinusitis are mucopurulent nasal discharge, nasal obstruction or congestion, and facial pain, fullness, or pressure lasting less than 4 weeks. Other symptoms and signs include postnasal drip (that may lead to coughing), pressure over the involved sinus, malaise, hyposmia, anosmia, fever, maxillary dental pain, and ear fullness or pressure. Acute sinusitis typically progresses over a period of 7 to 10 days and resolves spontaneously. During the first 3 to 5 days of illness, it may be difficult to differentiate acute viral from acute bacterial sinusitis. The bacterial origin is suggested by worsening symptoms within 10 days, persistent symptoms after 10 days, or “double sickening,” which refers to patients who improve initially, only to have worsening sinus congestion and discomfort. Bacterial infection is also associated with more severe presentations and extrasinus manifestations of infection.  

Chronic sinusitis is slow in onset, prolonged in duration (greater than 12 weeks), and recurrent in frequency. Symptoms can be nonspecific but are generally similar to those of acute disease. Symptoms of chronic disease may also include chronic cough, fetid breath, laryngitis, bronchitis, and worsening asthma. Recurrent acute sinusitis is diagnosed when four or more episodes of acute bacterial infection, without its signs or symptoms between episodes, occur per year. The presentation and treatment of recurrent acute disease is similar to that for acute bacterial sinusitis.  

Invasive fungal sinusitis (mucormycosis) is an aggressive opportunistic rhinocerebral infection that affects immunocompromised hosts. Mucormycosis (*Rhizopus*) is generally associ-
ated with fever, localized nasal pain, and cloudy rhinorrhea. On examination, the affected tissue (usually the turbinates) appears gray, friable, anesthetic, and nonbleeding because of infarction caused by mucormycotic angioinvasion. In advanced cases the affected tissues are necrotic and black, and the infection spreads beyond the sinus.34,35

**Diagnostic Strategies**

Physical examination is best performed after the application of a topical decongestant. Mucosal erythema and edema are usually present. Purulent discharge from the nasal meatus may be observed if the sinus ostia are not completely obstructed. In the setting of acute sinusitis, nasal and nasopharyngeal cultures correlate poorly with cultures of sinus aspirates and cultures obtained at the time of open antrostomy and do not differentiate between acute viral and acute bacterial infections. Culture and biopsy are indicated in suggested chronic, recurrent acute, and fungal sinusitis.32,33 Radiographic examination should be limited to diagnosis of chronic or recurrent acute sinusitis, cases of questionable diagnoses, those with unresponsive disease, or investigation of complications. Axial and coronal CT is the imaging modality of choice. CT findings suggestive of sinusitis include air-fluid levels, sinus opacification, sinus wall displacement, and mucosal thickening (Fig. 73-9). CT is sensitive, though not specific. Incidental sinus mucosal thickening is seen in 40% of asymptomatic patients, and abnormal CT findings can also be noted in just half of patients with seasonal allergies. CT with IV contrast or MRI may be required to evaluate complications of rhinosinusitis (central nervous system, orbital, or other extrasinus infections) and are helpful in determining alternative diagnoses. Plain films have limited utility in the diagnosis of rhinosinusitis; positive findings are similar to those of CT. Sinus endoscopy is another option.32,33

**Differential Considerations**

Rhinitis can be differentiated from sinusitis by the increased response of nasal obstruction to treatment, clear nasal discharge, and absence of pain. Rhinitis does not lead to ostial obstruction, and thus patients do not complain of facial pain.

Malignancy, tension headache, vascular headache, foreign body, dental disease, brain abscess, epidural abscess, meningitis, and subdural empyema may also present in a manner similar to sinusitis.

**Management**

Analgesics, antipyretics, and decongestants play important roles in the symptomatic management of sinusitis. A large proportion of cases of viral and bacterial sinusitis resolve spontaneously, and antibiotic therapy offers only modest incremental benefit.32,33,36 Most patients do not require antibiotics, and antibiotics should be reserved for those with symptoms and signs of sinusitis who have not improved after 7 days, who worsen despite adequate symptomatic treatment, or who have moderate to severe symptoms, including fever and purulent discharge, strongly suggestive of bacterial sinusitis, regardless of the duration of symptoms.32,33,36 Patients who are at high risk for severe infection or complications should also be considered for antibiotic therapy. The choice of antibiotics must consider β-lactamase production and multidrug-resistant pneumococci. Amoxicillin administered for 7 to 10 days is still the first-line agent, but benefits are limited and treatment failures occur in areas with a high percentage of β-lactamase-producing bacteria.32,33 High-dose amoxicillin should be considered for patients who have a child in daycare in the household. Penicillin-allergic patients may be treated with trimethoprim-sulfamethoxazole or a macrolide antibiotic. A 3-day course of trimethoprim-sulfamethoxazole or azithromycin and decongestants may be as effective as the standard 10-day antibiotic course.32,33 Failure of symptoms to resolve after 7 days of therapy, or antibiotic usage in the past 4 to 6 weeks, necessitates a change to a broader spectrum antibiotic and reassessment of the patient to confirm the diagnosis of acute bacterial sinusitis. Appropriate management includes a 10- to 14-day course of high-dose amoxicillin-clavulanate, cefuroxime axetil, other second- or third-generation cephalosporins, clindamycin alone or in combination with ciprofloxacin, sulfamethoxazole, azithromycin, clarithromycin, or one of the respiratory fluoroquinolones (levofloxacin, moxifloxacin, gemifloxacin). Metronidazole may be added to any of these regimens to increase activity against anaerobic organisms. Antibiotics for chronic sinusitis should be effective against anaerobic and β-lactamase-producing bacteria. Treatment of life-threatening complications requires consultation and high-dose IV antibiotics, including cefuroxime, ceftriaxone, or ampicillin-sulbactam.32,33,36 Antifungals may be beneficial in the treatment of chronic sinusitis.32,33,36

The goal of decongestant therapy is to reduce tissue edema, facilitate drainage, and maintain patency of the sinus ostia. Decongestants are available in topical and systemic preparations, both of which should be used simultaneously in conjunction with appropriate antibiotics.32,33 Topical agents provide more relief than systemic decongestants. Topical agents include 0.5% phenylephrine hydrochloride and 0.05% oxymetazoline hydrochloride. Topical agents should be used for only 3 to 5 days. Extended use results in rebound vasodilation and nasal obstruction, a condition termed *rhinitis medicamentosa*. Systemic oral adrenergic agonists (e.g., phenylpropanolamine or pseudoephedrine) reduce nasal blood flow and congestion. These medications should be used cautiously in patients taking tricyclic antidepressants, monoamine oxidase inhibitors, and nonselective beta-adrenergic blockers.32,33 Antihistamines should be reserved for the treatment of allergic sinusitis because these agents may impede sinus drainage. Second-generation H1-antagonists are preferred due to their better side effect profile. Topical, but not systemic, steroids

![Figure 73-9. Computed tomographic scan showing bilateral maxillary sinus opacification.](image-url)
are indicated for chronic and allergic sinusitis. Systemic steroids may be indicated in allergic and chronic sinusitis with nasal polyps.\textsuperscript{32,34,38}

Saline nasal irrigation is beneficial for treating acute bacterial, recurrent acute, and chronic sinusitis. Saline irrigation may be efficacious for the prevention of sinusitis. Hypertonic saline preparations have superior anti-inflammatory properties and may be more effective than normal saline.\textsuperscript{32,33}

**Complications**

Most cases of uncomplicated acute bacterial sinusitis can be treated on an outpatient basis with systemic decongestants, topical decongestants, and oral antibiotics. Failure of definitive antibiotic therapy suggests that the patient’s sinusitis has extended to the chronic stage and necessitates referral to an otolaryngologist. Treatment of chronic sinusitis requires a prolonged (3–6 week) course of antibiotics.

Frontal or sphenoid sinusitis with air-fluid levels may require hospitalization. A previously healthy, nontoxic patient with good home support can be treated as an outpatient but should return immediately for any symptoms or signs of complications, including severe headache, neurologic changes, or visual changes. Patients who appear toxic, who are immunoincompetent, or who have poor home resources require hospital admission and IV antibiotics.

Sinusitis is associated with an increased incidence of bronchitis and asthma. Infectious processes of the sinuses can spread to the orbit or central nervous system and can be fulminant. Sinusitis may extend to involve the bones and soft tissues of the face and orbit. Facial and periorbital cellulitis, periorbital abscess, optic neuritis, blindness, and orbital abscess may develop. Patients with orbital complications may have marked swelling, proptosis, decreased ocular motility, and decreased visual acuity. Sinusitis may also lead to intracranial complications. Meningitis, cavernous sinus thrombosis, epidural or subdural empyema, and brain abscess occur. Intracranial involvement may result in headache, decreased sensorium, or focal neurologic deficits and has a rapidly progressive course. Acute fulminant fungal sinusitis requires IV antifungal therapy and aggressive surgical débridement.\textsuperscript{32,33,35} Complications of mucormycosis are directly related to delay in diagnosis and treatment. This opportunistic fungal infection rapidly progresses to involve the central nervous system and is associated with high morbidity and mortality rates.

**KEY CONCEPTS**

- A severe sore throat with surprisingly minimal findings on examination of the oropharynx suggests serious soft tissue infection such as epiglottitis, retropharyngeal abscess, or peritonsillar abscess.
- Deep space cellulitis is difficult to differentiate from deep space abscess and may require needle aspiration after CT or MRI.
- Keep patients with upper airway infections in a position of comfort.
- Posterior parapharyngeal abscess may involve the cervical sympathetic chain, carotid artery, or internal jugular vein.
- Aspiration and incision of a carotid artery aneurysm thought to be a parapharyngeal abscess may be disastrous.
- Resolving pharyngitis followed by severe sepsis, right-sided endocarditis, or aspiration pneumonia should suggest septic thrombosis of the internal jugular vein.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
Pneumonia is the seventh leading cause of death and the leading cause of death from infectious disease in the United States. The annual incidence of community-acquired pneumonia (CAP) in the United States ranges from 2 to 4 million, resulting in approximately 500,000 hospital admissions. Most cases of CAP are managed in the outpatient setting and the mortality is low (<1%), but pneumonia requiring hospitalization is associated with a much higher mortality rate (approximately 15%). Most deaths occur in elderly or immunosuppressed patients. Pneumonia remains challenging because of an expanding spectrum of pathogens, changing antibiotic resistance patterns, the availability of newer antimicrobial agents, and increasing emphasis on cost-effectiveness and outpatient management.

The epidemiology of CAP is changing. As the percentage of the population older than age 65 years continues to increase, the incidence of pneumonia is expected to increase. An increasing number of patients are taking immunosuppressive drugs related to treatment of malignancy, transplantation, or autoimmune disease, resulting in more cases of pneumonia due to other opportunistic pathogens. Patients with acquired immunodeficiency syndrome (AIDS) are at increased risk of infection with *Streptococcus pneumoniae*, *Mycobacterium tuberculosis*, or *Pneumocystis jirovecii* (previously known as *Pneumocystis carinii*). Antibiotic resistance is more common among *S. pneumoniae* and other pathogens. In addition, the threat exists of respiratory infections due to biologic terrorism or newly recognized pathogens that have the potential to spread quickly through international travel.

Identification of a specific etiology of pneumonia is extremely difficult within the time frame of an emergency department (ED) visit. Even after a thorough inpatient evaluation, a specific pathogen is never identified in many patients with pneumonia. When pneumonia is diagnosed, the priorities in the ED are to initiate appropriate empirical antibiotic therapy based on the most likely pathogens, provide appropriate respiratory support, assess the severity of disease, and recognize indications for hospitalization.

**Principles of Disease**

Despite the constant presence of potential pathogens in the respiratory tract, the lungs are remarkably resistant to infection. The alveolar surface of the lungs covers an area of approximately 140 m². Approximately 10,000 L of air passes through the respiratory tract each day, and typical ambient air can contain hundreds to thousands of microorganisms per cubic meter. Numerous potential respiratory tract pathogens may colonize the oropharynx and upper airways. Although the cough and laryngeal reflexes prevent most large particulate matter from entering the lower respiratory tract, aspiration of oropharyngeal contents may be a common occurrence during normal sleep. Despite these hazards, healthy lungs are usually a virtually sterile environment.

The development of clinical pneumonia requires a defect in host defenses, the presence of a particularly virulent organism, or the introduction of a large inoculum of organisms. If the challenge of invading organisms overwhelms host defenses, microbial proliferation leads to inflammation, an immune response, and clinical pneumonia. If host defenses are weak, a minimal challenge may lead to the development of pneumonia.

The mouth normally contains numerous microorganisms. Saliva contains approximately $10^9$ bacteria/mL, with anaerobic organisms predominating. *Bacteroides* and *Fusobacterium* spp. are the most common anaerobic organisms. *Streptococci* are the most common aerobic organisms, but staphylococci, *Haemophilus* sp., *Moraxella catarrhalis*, and *Neisseria* sp. are also found. Anything that upsets the balance of normal oral flora may permit the growth of more virulent organisms. Systemic illness may alter epithelial binding of oral flora, leading to increased colonization with aerobic gram-negative bacilli. Antimicrobial therapy can also adversely alter normal oral flora.

Host defenses can be impaired in many ways. An altered level of consciousness (e.g., intoxication, stroke, seizures, and anesthesia) can suppress protective airway reflexes and lead to aspiration of oropharyngeal contents into the lower respiratory tract. Interventions that bypass the usual defenses of the upper airways, such as endotracheal intubation, nasogastric intubation, and respiratory therapy devices, predispose to infection. Cigarette smoking damages mucociliary function and macrophage activity. Viral infections of the respiratory tract may destroy respiratory epithelium and predispose it to bacterial infection. Increased risk of bacterial pneumonia after influenza or other viral respiratory infections is well described. The elderly are at increased risk of pneumonia related to decline of mucociliary clearance, elastic recoil of the lungs, and humoral and cellular immunity. Human immunodeficiency virus (HIV) infection impairs humoral and cellular immunity.
If an infectious organism reaches the alveoli and begins replicating, a series of host immune responses occurs that ultimately may lead to the development of clinical pneumonia. As antigens of the infecting organism are identified by the host, cytokines, such as interleukin-1, interleukin-8, and tumor necrosis factor, are produced that mediate the inflammatory response. Transudation of plasma fluids into the lungs allows entry of IgM and IgG for bacterial opsonization, complement activation, agglutination, and neutralization. Neutrophils are recruited into the lungs to ingest and kill the infecting organisms. Cell-mediated immunity plays an important role in defense against certain pathogens, such as viruses and intracellular organisms such as *Mycobacterium* and *Legionella* spp. As fluids and inflammatory cells enter the alveolar spaces to combat the infection, the patient develops the clinical and radiographic signs of pneumonia.

### Etiologic Agents

The challenge with pneumonia lies in identifying the etiologic agent rather than in diagnosis of pneumonia. It is extremely difficult to determine with a high degree of certainty the specific organism responsible for pneumonia, especially within the time frame of an ED evaluation. Empiric therapy must be chosen with activity against the spectrum of likely pathogens based on the overall clinical picture.

Difficulty in determining the specific etiology of pneumonia exists even with advanced microbiologic and serologic testing that is not generally available during an ED evaluation. In community-acquired pneumonia, a microbial etiology cannot be determined in one third to one half of cases, even after thorough investigation. In hospitalized adults with CAP, pathogens such as *S. pneumoniae* and *Haemophilus influenzae*, referred to as “typical” pathogens, account for approximately one fourth of cases. *Legionella*, *Mycoplasma*, and *Chlamydia* spp. (previously known as *Chlamydia*), referred to as “atypical” pathogens, are also common. Testing for common viral agents reveals a viral etiology in approximately 18% of cases, with influenza and parainfluenza viruses most common. Adults who require intensive care unit (ICU) admission have *S. pneumoniae* as the most common pathogen, with even higher prevalence among fatal cases. *Legionella* spp., *Staphylococcus aureus*, and aerobic gram-negative bacilli also appear to be relatively more common among adults with severe CAP. Atypical organisms such as *Mycoplasma* sp. or viruses account for a relatively higher proportion of pneumonia in patients who have milder illness that is amenable to outpatient therapy. However, atypical organisms occur with significant frequency in patients with severe illness requiring hospitalization, particularly due to *Legionella* infection. Co-infection, such as with *Chlamydia pneumoniae* and *S. pneumoniae*, is also well recognized.

*Streptococcus pneumoniae* is a gram-positive coccus that is the most common etiology of CAP among adults. It colonizes the nasopharynx in 40% of healthy adults. Although this organism can cause pneumonia in healthy people, patients with a history of diabetes, cardiovascular disease, alcoholism, sickle cell disease, splenectomy, and malignancy or other immunosuppressive illness are at increased risk. A vaccine containing the 23 capsular polysaccharides of pneumococcal types most commonly associated with pneumonia reduces the likelihood of serious pneumococcal infection. It is recommended for people at increased risk because of underlying illness or age older than 65 years. Many ED patients have not received pneumococcal vaccine, and vaccinating eligible patients in this setting seems to be feasible and effective. A heptavalent protein-conjugate pneumococcal vaccine effectively reduces invasive pneumococcal disease and pneumonia in infants and young children.

*Haemophilus influenzae*, the second most frequently isolated organism in CAP among adults, is a pleomorphic gram-negative rod. It is a common pathogen in adults with chronic obstructive pulmonary disease (COPD), alcoholism, malnourishment, malignancy, or diabetes.

Although *Staphylococcus aureus* remains an uncommon cause of CAP, community-associated strains of methicillin-resistant *S. aureus* (CA-MRSA) are emerging as a cause of severe pneumonia in previously healthy adults and children. This is often associated with influenza. *Staphylococcal* pneumonias are often necrotizing, with cavitation and pneumatocele formation. Intravenous drug users may develop hematogenous spread of *S. aureus* that involves both lungs with multiple small infiltrates or abscesses (e.g., tricuspid endocarditis resulting in septic pulmonary emboli). Other pyogenic bacterial etiologies include *Moraxella catarrhalis*, a gram-negative diplococcus that can be associated with lower respiratory tract infections in patients with COPD.

*Klebsiella pneumoniae* is a gram-negative rod that rarely causes disease in a normal host and accounts for a small percentage of CAPs. It may cause severe pneumonia in debilitated patients with alcoholism, diabetes, or other chronic illness. There is a high incidence of antibiotic resistance since the organism is often hospital acquired.

*Mycoplasma pneumoniae* is one of the most common causes of CAP in previously healthy patients younger than age 40 years. Another important organism in CAP is *C. pneumoniae*, an intracellular parasite that is transmitted between humans by respiratory secretions or aerosols. Seroprevalence studies indicate that virtually everyone is infected with *C. pneumoniae* at some time and that re-infection is common. *Chlamydia pneumoniae* is a relatively common etiology of CAP, especially in older adults. It accounts for at least 8% of cases, although this is an underestimate due to difficulty in diagnosing infection with this organism.

At least 30 species of *Legionella* have been isolated since the 1976 convention-related outbreak in Philadelphia, from which the organism derives its name. At least 19 are known human pathogens. *Legionella* is an intracellular organism that lives in aquatic environments. There is no person-to-person transmission. Although it is implicated in point outbreaks related to cooling towers and similar aquatic sources, the organism also lives in ordinary tap water and is underdiagnosed as an etiology of CAP. *Legionella* prevalence seems to vary greatly by region.

Lower respiratory infections due to anaerobic organisms generally result from the aspiration of oropharyngeal contents with large amounts of bacteria. These infections are typically polymicrobial, including *Peptostreptococcus*, *Bacteroides*, *Fusobacterium*, and *Prevotella* spp. Presentation is often subacute or chronic and may be difficult to distinguish clinically from other etiologies of pneumonia. Clinical factors that suggest an anaerobic infection include risk factors for aspiration, such as central nervous system depression or swallowing dysfunction; severe periodontal disease; fetid sputum; and the presence of a pulmonary abscess or empyema.

Viral pneumonias are common in infants and young children and are recognized as an important cause of pneumonia in adults. Respiratory syncytial virus and parainfluenza viruses are the most common causes of pneumonia in infants and small children, occurring mostly during autumn and winter. Influenza viruses are the most common cause of viral pneumonia in adults. Winter influenza outbreaks, usually due to influenza type A, may cause 40,000 deaths annually in the United States. More than 90% occur in people age 65 years or older.
Metapneumovirus is a paramyxovirus that seems to be an important cause of viral pneumonia in children and adults. Cytomegalovirus (CMV) primarily causes pneumonia in immunosuppressed patients, such as transplant recipients. Varicella-zoster virus causes pneumonia that seems to be more common and more severe in adults. Predisposing factors include smoking or pregnancy. Severe acute respiratory syndrome (SARS) is a respiratory illness due to a coronavirus identified in Southeast Asia. SARS is associated with a high case fatality rate (approximately 10–15% overall and higher in the elderly).

Fungal infections due to organisms such as Histoplasma capsulatum, Blastomyces dermatitidis, and Coccioides immitis commonly present as pulmonary disease. These organisms are present in the soil in various geographic areas of the United States: *H. capsulatum* in the Mississippi and Ohio River valleys, *C. immitis* in desert areas of the Southwest, and *B. dermatitidis* in a poorly defined area extending beyond that of *H. capsulatum*. These infections should be considered in people in appropriate geographic areas, especially in those who are near activities that disturb the soil, such as construction or dirt bike riding. Clinical presentation varies from an acute or chronic pneumonia to asymptomatic granulomas and hilar adenopathy.

_Pneumocystis_ pneumonia (PCP) occurs in compromised hosts, principally people with AIDS or malignancy. Although _P. jirovecii_ is often classified as a protozoan, biochemical evidence indicates that it is more closely related to fungi. PCP is one of the most common presentations leading to a diagnosis of HIV infection and AIDS. Patients with pulmonary complaints should be questioned about HIV risk factors, and clinicians should search for signs of HIV-related immunosuppression, such as weight loss, lymphadenopathy, and oral thrush. PCP typically presents subacutely with fatigue, exertional dyspnea, nonproductive cough, pleuritic chest pain, and fever.

_Mycobacterium tuberculosis_ is a slow-growing bacterium transmitted between people by droplet nuclei produced from coughing and sneezing. _Mycobacterium tuberculosis_ survives within macrophages as a facultative intracellular parasite and may remain dormant in the body for many years. Active tuberculosis (TB) develops within 2 years of infection in approximately 5% of patients, and another 5% develop reactivation disease at some later time. Reactivation is more likely to occur in people with impaired cell-mediated immunity, such as patients with diabetes, renal failure, immunosuppressive therapy, malnutrition, or AIDS. Approximately one third of the world’s population is infected with _M. tuberculosis_. Approximately 8 million new cases of active disease develop annually, resulting in 3 million deaths worldwide. An estimated 10 to 15 million people in the United States (3–5% of the population) are infected with TB. Multidrug-resistant strains of _M. tuberculosis_ are found in increasing numbers, especially among immigrants from Southeast Asia and AIDS patients.

### Unusual Causes of Pneumonia

Hantaviruses are endemic in several areas of the United States and can cause a syndrome of severe respiratory distress and shock. Infection occurs from inhalation of aerosols contaminated with rodent urine and feces. Patients are typically healthy adults with a prodrome of fever, myalgia, and malaise followed several days later by the onset of respiratory distress. Hypoxia may progress rapidly, requiring ventilatory support. Characteristic laboratory findings include thrombocytopenia, hemococoncentration, and leukocytosis with atypical lymphocytes. Chest radiographs show bilateral interstitial lung infiltrates that are more pronounced in dependent areas. Treatment is supportive, including the use of extracorporeal membrane oxygenation. There is no known effective antiviral therapy.

Plague, caused by _Yersinia pestis_, is endemic in many areas of the world, including the southwestern United States. It is an agent that could be used for biologic terrorism, but it also occurs naturally in people bitten by fleas from infected rodents or carnivores. Hematogenous spread may lead to pneumonia that is highly contagious and has a high mortality.

A number of zoonotic organisms cause pneumonia. Tularemia, caused by the bacterium _Francisella tularensis_, is spread by contact with body fluids of an infected mammal (especially rabbits) or the bite of an infected arthropod. Illness usually begins with an ulcerated skin lesion and painful regional lymphadenopathy. Some patients have a typhoidal form with only fever, malaise, and weight loss. Pneumonia may occur with either form, presenting as a nonproductive cough and patchy infiltrates on a chest radiograph. Psittacosis can spread to humans from birds infected with _Chlamydia psittaci_. Illness often begins rapidly with chills, high fever, myalgias, and nonproductive cough. Severe headache is often the major complaint. Splenomegaly is often present. Q fever is caused by the rickettsial organism _Coxiella burnetii_. It is most common in people with occupational exposure to cattle or sheep or parturient animals, including cats. Severe headache occurs in approximately 75% of cases. Q fever is rarely fatal. Other zoonotic pulmonary infections include _Rhodococcus equi_ associated with exposure to horses and _Bordetella bronchiseptica_ associated with exposure to ill dogs (“kennel cough”).

### CLINICAL FEATURES

The ED evaluation should focus on establishing the diagnosis of pneumonia and determining the presence of epidemiologic and clinical features that would influence decisions regarding hospitalization and antibiotics. Key history includes the character and pattern of symptoms, the setting in which the pneumonia is acquired, geographic or animal exposures, and host factors that predispose to certain types of infections and are associated with outcome.

Pneumonia generally presents as a cough productive of purulent sputum, shortness of breath, and fever. In most healthy older children and adults, the diagnosis can be reasonably excluded on the basis of history and physical examination, with suspected cases confirmed by chest radiography. The absence of any abnormalities in vital signs or chest auscultation substantially reduces the likelihood of pneumonia. However, no single isolated clinical finding is highly reliable in establishing or excluding a diagnosis of pneumonia.

Elder or debilitated patients with pneumonia often present with nonspecific complaints but not the classic symptoms. Pneumonia commonly presents in the elderly as acute confusion or a deterioration of baseline function. Elder patients are more likely to have advanced illness at the time of presentation and may present with sepsis in the absence of a previous syndrome suggestive of pneumonia. Rarely, patients with lower lobe pneumonia present with a complaint of abdominal or back pain. The diagnosis may be more difficult in infants and small children who are unable to give an adequate history. Pneumonia may present in infants as a fever associated with irritability, tachypnea, tachycardia, intercostal retractions, nasal flaring, or grunting. Cough may be minimal or absent.

Pneumonia can be divided based on clinical patterns into typical pneumonia caused by pyogenic bacteria, such as *S. pneumoniae* or *H. influenzae*, and atypical pneumonia caused by organisms such as _Mycoplasma_ and _Chlamydia spp_. This division is artificial, and a clear differentiation between these two types of pneumonia on clinical grounds alone is impossi-
ble. Certain clinical factors are often said to be suggestive of atypical organisms. Factors studied prospectively and found not to be more frequent with atypical pneumonias than with pyogenic bacterial etiologies include gradual onset, viral prodrome, absence of rigors, nonproductive cough, lower degree of fever, absence of pleurisy or consolidation, low leukocyte count, and an ill-defined infiltrate on a chest radiograph. Although it is impossible to determine with a high degree of certainty the specific etiology of pneumonia without results of microbiologic or serologic tests, certain clinical factors suggest that a specific pathogen should be considered.

The classic presentation of pneumococcal pneumonia is the abrupt onset of a single shaking chill followed by fever, cough productive of rust-colored sputum, and pleuritic chest pain. Many patients do not exhibit the classic pattern. Patients often have a preceding upper respiratory illness, and the onset of pneumonia may be insidious, especially in the elderly or with underlying lung disease. Patients with a history of asplenia, sickle cell disease, AIDS, multiple myeloma, or agammaglobulinemia are at increased risk of pneumococcal bacteremia and sepsis with high mortality rates. Extrapulmonary complications (e.g., meningitis, endocarditis, or arthritis) may rarely be present. Adults with chronic lung disease who develop pneumonia due to *H. influenzae* typically present with an insidious worsening of baseline cough and sputum production, and bacteremia is rare. *Klebsiella pneumoniae* may cause severe pneumonia in elderly or debilitated patients. Sputum is often described as “currant jelly” because of the necrotizing, hemorrhagic nature of the infection. Abscess formation, empyema, and bacteremia are common with this organism, and mortality is high.

Atypical pneumonia is caused by organisms such as *M. pneumoniae*, *C. pneumoniae*, viruses, *Legionella* sp., or rickettsiae such as *C. burnetii*. Mycoplasmal infection usually begins as a flulike illness with headache, malaise, and fever. Cough is usually nonproductive but may sometimes produce clear or purulent sputum. Skin lesions, including maculopapular, vesicular, urticarial, or erythema multiforme-type rashes, are common, especially in younger patients. Although bullous myringitis is described as a classic finding, it is not specific for mycoplasmal infection and is present in only a few cases. Common physical findings include pharyngeal erythema, cervical adenopathy, and scattered rales and rhonchi. Rare extrapulmonary manifestations include pericarditis, glomerulonephritis, aseptic meningitis, and Guillain-Barre syndrome. Patients generally do not appear toxic, and most can be treated as outpatients. Although mucopurulent sputum generally indicates the presence of pyogenic bacterial pneumonia or bronchitis, it may also be present with mycoplasmal or viral pneumonia. Viral pneumonia in adults is often preceded by symptoms of upper respiratory infection, such as rhinitis or sore throat. Cough is usually nonproductive, and pleuritic chest pain is less common than with bacterial pneumonia.

Most *C. pneumoniae* infections in young adults cause a minor, self-limited upper respiratory illness that is subacute in onset. This organism is also associated with bronchitis, wheezing, sinusitis, pharyngitis, and atherosclerosis. Development of radiographically evident pneumonia is more common in the elderly, in contrast to the common perception that atypical pneumonias occur in the young.

Some patients with *Legionella* infection have a mild, self-limited atypical pneumonia presentation. Older patients, smokers, and those with chronic disease or immunosuppression are more prone to develop the more acute and severe systemic illness of legionnaires’ disease. Gastrointestinal symptoms, such as diarrhea and abdominal cramping, are sometimes prominent.

In addition to age, the presence of underlying illness, and presenting symptoms, the setting of acquisition of pneumonia may provide clues to likely etiologies. CAP that occurs in otherwise healthy individuals is likely to be due to viruses, *Mycoplasma* sp., or *S. pneumoniae*. *Staphylococcus aureus*, including CA-MRSA, can cause severe pneumonia associated with influenza. Hospitalized patients may develop pneumonia due to agents that are uncommon in CAP, such as Enterobacteriaceae, *Pseudomonas aeruginosa*, and *S. aureus*. Healthy patients in an institutional setting, such as a dormitory or military barracks, are likely to have pneumonia due to *Mycoplasma* sp. or viruses.

Patients with underlying lung disease, especially COPD, constitute an important group likely to develop pneumonia. The lower respiratory tract of these patients is commonly colonized with organisms such as *S. pneumoniae*, *H. influenzae*, and *M. catarrhalis*. Cystic fibrosis patients are prone to pneumonia due to *P. aeruginosa* or *S. aureus*. Defective mucociliary clearance in both of these groups makes them highly susceptible to repeated episodes of pneumonia.

Patients with immunosuppression due to hematologic malignancy, patients receiving chemotherapy for malignancy, and transplant recipients are prone to pulmonary infections with a wide variety of organisms. In addition to the usual pathogens, these patients may develop pneumonia secondary to viruses such as CMV, varicella, or herpes simplex virus. They are also more likely to develop pneumonia due to aerobic gram-negative bacilli, fungi such as *Candida* sp. or *H. capsulatum*, and *P. jiroveci*.

Patients in nursing homes or other extended-care facilities are at increased risk for infection with resistant organisms such as *P. aeruginosa*, *K. pneumoniae* (including strains producing extended-spectrum β-lactamases), *Acinetobacter* species, and hospital-associated strains of MRSA. Other risk factors for infection with multidrug-resistant pathogens include (1) hospitalization for 2 or more days in an acute care facility within 90 days of infection; (2) patients who attended a hemodialysis clinic; and (3) patients who received intravenous antibiotic therapy, chemotherapy, or wound care within 30 days of infection. Any patient with pneumonia that fulfills any one of these historical features, including patients from a nursing home or long-term care facility, is designated as having health care–associated pneumonia (HCAP). HCAP is associated with a greater likelihood of resistant pathogens such as *Pseudomonas* and MRSA, and mortality is higher than that for CAP.

### Diagnostic Strategies

Although many chest radiographs are obtained unnecessarily for patients with upper respiratory tract infections or bronchitis, it is difficult to identify a set of specific criteria to direct test ordering that is better than the clinical judgment of an experienced physician. A routine chest radiograph for all patients who present with cough is not necessary; chest radiography may be reserved for patients who have other suggestive findings (e.g., fever, tachycardia, oxygen desaturation, or an abnormal lung examination). Among patients suspected to have pneumonia, these clinical findings are prospectively validated and are better predictors of a radiographic infiltrate than physician judgment. Patients with serious underlying disease, patients with severe sepsis or shock, and patients in whom hospitalization is considered should have chest radiography performed. Computed tomography (CT) of the chest is more sensitive than plain radiography for detecting the presence of pulmonary consolidation, although the natural history of CT-positive, plain radiograph-negative pneumonia is not clear. Young, healthy adults with a presumptive diagnosis of pneu-
Pneumonia, who will be treated as outpatients, may have a chest radiograph deferred unless there is a suspicion of immunocompromise or other unusual features of disease. A chest radiograph should be obtained subsequently if there is a poor initial response to treatment. Routine performance of chest radiography for patients with exacerbation of chronic bronchitis or COPD is of low yield and may be limited to patients with other signs of infection or congestive heart failure. Studies of infants with fever show that a routine chest radiograph is of low yield in the absence of other symptoms or signs of lower respiratory tract infection (e.g., abnormal auscultation or elevated respiratory rate).17

Although the causative agent cannot be determined solely by the results of chest radiography, certain radiographic patterns may suggest the possibility of specific pathogens. In pyogenic bacterial pneumonias, radiographs usually show an area of segmental or subsegmental infiltration and air bronchograms (Fig. 74-1). Lobar consolidation is present in a few cases of bacterial pneumonia, often due to pneumococcus or *Klebsiella*. A dense lobar infiltrate with a bulging fissure appearance on a chest radiograph is often described with pneumonia due to *Klebsiella*, but this finding is nonspecific, and most cases present as a subtler bronchopneumonia. Pneumonia resulting from spread of infection along the intralobular airway results in fluffy or patchy infiltrates in the involved areas of the lung. A wide variety of bacteria and agents such as *Chlamydophila* sp., *Mycoplasma* sp., *Legionella* sp., viruses, and fungi may cause this pattern.

An interstitial pattern on a chest radiograph (Fig. 74-2) typically is caused by *Mycoplasma* sp., viruses, or *P. jirovecii*. Tiny nodules disseminated throughout both lungs represent a miliary pattern typical of granulomatous pneumonias, such as TB or fungal disease. The location of infiltrates may also give a clue to the etiology. Aspiration pneumonia occurs in dependent areas of the lung, most commonly the superior segments of the lower lobes or posterior segments of the upper lobes. Pneumonias produced by hematogenous spread (e.g., *S. aureus*) tend to be peripheral. Apical infiltrates suggest TB.

The presence of additional radiographic features in association with infiltrates may suggest a specific etiology. An infiltrate associated with hilar or mediastinal adenopathy suggests the presence of TB or fungal disease or may indicate pneumonia associated with a neoplasm. Bacteria most likely associated with cavitation (Fig. 74-3) are anaerobes, aerobic gram-negative bacilli, and *S. aureus*. Cavitation also may be present in fungal disease or TB and with noninfectious processes (e.g., malignancy and pulmonary vascular disease). Pneumato-
celes or spontaneous pneumothorax may be seen in AIDS patients with PCP. Pleural effusions occur with a wide variety of organisms, including many types of pyogenic bacterial pneumonias, *Chlamydia sp.*, *Legionella sp.*, and TB. Anaerobic infections associated with an effusion are especially prone to development of empyema. The diagnosis and aspiration of pleural effusions can be aided by use of ED bedside ultrasonography.

Radiographic findings are nonspecific for predicting a particular infectious etiology. *Mycoplasma* pneumonia may present as a dense infiltrate, or pneumococcal pneumonia may present as a diffuse interstitial infiltrate. Immunocompromised patients are particularly prone to having atypical radiographic appearances. Rarely, patients with a clinical picture strongly suggestive of pneumonia have a normal chest radiograph, and some are found to have an infiltrate within the next 24 to 48 hours. The absence of findings on a chest radiograph should not preclude the use of antimicrobial therapy in appropriate patients with a clinical diagnosis of pneumonia. Whether the state of hydration can affect the radiographic appearance of pneumonia is controversial. Although severe dehydration theoretically could result in a diminished exudative response by decreasing blood volume and hydrostatic pressure, this has not been shown experimentally.

Laboratory studies also are nonspecific for identifying the etiology of pneumonia. Although the finding of a white blood cell count (WBC) greater than 15,000/mm³ increases the probability of the patient having a pyogenic bacterial etiology rather than a viral or atypical etiology, the predictive value of this finding depends on the stage of the illness and likely prevalences of various etiologies. This is neither sensitive nor specific enough to aid decisions regarding therapy in an individual patient. A WBC may be helpful if it yields evidence of immunosuppression, such as neutropenia, or if it reveals lymphopenia that may indicate immunosuppression from AIDS. Basic metabolic panels may help identify patients with renal or hepatic dysfunction or metabolic acidosis associated with sepsis. These findings predict a complicated course and influence decisions regarding disposition, choice of antimicrobial agents, and dosages.

The assessment of respiratory function with pulse oximetry is important in the evaluation of patients with pneumonia since clinical assessment of oxygenation can be inaccurate. Pulse oximetry should be obtained in any patient suspected to have pneumonia.

Sputum Gram’s stain rarely results in a change in therapy or outcome. Correlation between identification of pneumococcus on Gram’s stain and sputum culture results is poor, even when commonly used criteria for an adequate sputum specimen (<5 squamous epithelial cells and >25 WBC/high-power field) are applied. Gram’s stains are even less likely to show gram-negative pathogens, such as *H. influenzae*, and should not be relied on to rule out a gram-negative etiology. Empirical antimicrobial agents are usually highly clinically effective if chosen based on clinical information without sputum analysis. Guidelines for management of CAP from the Infectious Disease Society of America (IDSA) and American Thoracic Society (ATS) support limiting sputum Gram’s stain and culture to those patients with more severe disease or risk factors for unusual pathogens.

Routine blood cultures are of essentially no value in nonimmunocompromised adults with pneumonia, in whom there is a very low prevalence of noncontaminant bacteremia, and management is rarely changed based on the results. The follow-up of false-positive blood cultures is costly and labor-intensive, and it may lead to unnecessary use of antibiotics such as vancomycin or linezolid when results are initially reported as gram-positive cocci. Blood cultures should be obtained from immunocompromised patients, those with severe sepsis or shock, or those with risk factors for endovascular infection (e.g., prosthetic valves, intravenous drug use, or cavitary infiltrates). When cultures are drawn, they should be obtained prior to the initiation of antibiotics (although antibiotics should not be delayed for this reason).

Patients with a pleural effusion greater than 5 cm on lateral upright posterior-anterior chest radiograph should have a diagnostic thoracentesis performed, with fluid sent for cell count, differential, pH (pH < 7.2 predicts the need for a thoracostomy tube), Gram’s stain, and culture. For most patients, thoracentesis can be safely deferred until after hospital admis-
Pneumonia Associated with Human Immunodeficiency Virus Infection

The approach to an HIV-infected patient with pulmonary complaints must consider the likelihood of opportunistic lung infections. Although the use of highly active antiretroviral therapy (HAART) is decreasing the incidence of opportunistic infections among HIV-infected patients, individuals who are not under regular care often present to the ED. In the setting of a patient with risk factors for HIV but an unknown serologic status, a decision must be made as to the likelihood of AIDS and the need to search aggressively for opportunistic pathogens.

Respiratory infections are the most common type of opportunistic infection in AIDS patients. In addition to *P. jiroveci*, there is also an increased incidence of pneumonia due to *M. tuberculosis* and common bacterial pathogens such as *S. pneumoniae* and *H. influenzae*. The incidence of pneumococcal pneumonia is 7 to 10 times higher in HIV-infected people and the incidence of *H. influenzae* pneumonia is approximately 100 times higher than in non-HIV-infected individuals. Other less important causes of pneumonia in HIV-infected patients include *Mycobacterium avium* complex, CMV, aerobic gram-negative bacilli, *Cryptococcus neoformans*, and *Rhodococcus equi*.

Although some patients have known HIV infection or AIDS, many patients are unaware of their HIV status, and many are reluctant to volunteer that they have risk factors for HIV. The first crucial step in the diagnosis of PCP is the recognition that a patient may be at risk. If the possibility of HIV infection is established, the likelihood of immunosuppression must be determined. The potential for opportunistic pulmonary infection can be predicted by a recent absolute CD4 lymphocyte count less than 200/mm³. This count is often known by patients with recognized HIV infection or may be surmised by a peripheral total lymphocyte count less than 1000/mm³. In patients who do not know their HIV status, the presence of findings such as weight loss, hairy leukoplakia, and oral candidiasis strongly suggests immunosuppression.

Although patients with PCP may present with typical features of subacute onset of nonproductive cough, fever, shortness of breath, diffuse interstitial infiltrates on chest radiography, and arterial hypoxemia, 10 to 20% of patients subsequently proven to have PCP lack these findings. PCP usually has a subacute presentation characterized by nonproductive cough, exertional dyspnea, and weight loss. Tachypnea and tachycardia are usually present.

The classic radiographic findings in PCP are bilateral interstitial infiltrates that begin in the perihilar region. Radiographic manifestations of PCP can vary considerably, however, ranging from a normal appearance to dense consolidation. Lobar infiltrates, pleural effusions, hilar adenopathy, parenchymal nodules, and cavitary disease are also described. Hypoxemia, hypocapnia, and an increased arterial-alveolar oxygenation gradient are usually present. Serum lactate dehydrogenase is significantly elevated in AIDS patients with PCP compared to patients with non-PCP pneumonia. The demonstration of oxygen desaturation with mild exercise may be helpful in patients with more subtle presentations. Confirmation of the diagnosis of PCP requires sputum induction and staining and, in some cases, further invasive procedures, such as bronchoscopy with bronchoalveolar lavage or biopsy. In most settings, patients suspected to have PCP are admitted to the hospital and given presumptive therapy against PCP.

There is a broad differential diagnosis for pulmonary infiltrates in AIDS patients (Fig. 74-4). The bacterial pathogens most commonly responsible for pneumonia in these patients are the same pathogens most frequently encountered in immunocompetent individuals with CAP, but they may have an atypical appearance on chest x-ray. Because AIDS patients with pulmonary TB cannot be distinguished reliably from AIDS patients with other pulmonary infections at presentation, consider TB in all HIV-infected patients with respiratory complaints and initiate respiratory isolation. AIDS patients are also at risk for pneumonia due to other mycobacterial species (e.g., *M. avium* complex). Nevertheless, the finding of acid-fast bacilli in the sputum should prompt empirical therapy against *M. tuberculosis* until another mycobacterial species is definitively identified. AIDS patients are also at increased risk for pneumonia due to *Cryptococcus neoformans* or other fungi associated with geographic exposure. Kaposi’s sarcoma may also present with pulmonary infiltrates.

### Differential Diagnosis Considerations

The differentiation between upper and lower respiratory tract infections may be difficult. A chest radiograph helps differentiate between upper respiratory tract infection or bronchitis and pneumonia, but it is probably not necessary for all patients with cough and sputum production unless other factors are present that suggest the possibility of pneumonia or obscure its clinical diagnosis (e.g., toxic appearance, extremes of age, underlying illness, and abnormal chest examination).

Many noninfectious etiologies may result in inflammatory lung processes, including exposure to mineral dusts (e.g., silicosis), chemical fumes (e.g., chlorine and ammonia), toxic drugs (e.g., bleomycin), radiation, thermal injury, or oxygen toxicity. Immunologic diseases (e.g., sarcoidosis, Goodpasture’s syndrome, and collagen vascular disease) or hypersensitivity to environmental agents (e.g., farmer’s lung disease) may also result in pneumonia. Tumors may be confused with pneumonia radiographically or may present initially as a postobstructive infection or adenopathy with peripheral infiltrates. Lymphangitic spread of lung malignancy may resemble interstitial pneumonia.

### Aspiration

It is important to recognize the distinction between the acute aspiration of gastric contents or other liquids and bacterial pneumonia that may develop later as a complication of
aspiration. Aspiration of liquids into the lung disrupts surfactant and causes an inflammatory response that may lead to hypoxia and respiratory failure. Aspiration of acidic gastric contents is particularly damaging to lungs and is common in patients who are unconscious from intoxication or anesthesia or who have neurologic deficits. Patients may present initially with coughing or shortness of breath or may appear well initially and then develop respiratory dysfunction during the next several hours.

Acute aspiration of acidic fluid into the lungs may produce fever, leukocytosis, purulent sputum, and radiographic infiltrates that mimic bacterial pneumonia. Although many of these patients go on to develop bacterial pneumonia, prophylactic administration of antibiotics is controversial. Some studies indicate that prophylactic antibiotics do not seem to be beneficial and may select for resistant organisms. Antibiotics should be initiated if the patient develops signs of bacterial pneumonia, including new fever, expanding infiltrate appearing more than 36 hours after aspiration, or unexplained deterioration. Systemic corticosteroids for acute aspiration are of no benefit.

**MANAGEMENT**

The possibility of communicable disease should suggest early isolation. Patients with a history of TB exposure, suggestive symptoms (e.g., persistent cough, weight loss, night sweats, and hemoptysis), or belonging to a group at high risk for TB (e.g., homeless, intravenous drug user, alcoholic, HIV risk, and immigrant from high-risk area) should be given a mask and placed in respiratory isolation before evaluation, including chest radiography. EDs that frequently care for patients at risk for TB should consider triage protocols to identify these individuals rapidly before patients, visitors, or staff are unnecessarily exposed.

Antimicrobials should be administered in the ED for patients who are being admitted to the hospital. Timely administration of antimicrobials has been associated with improved outcomes for hospitalized pneumonia patients, although confounding factors limit the conclusions of these studies. A rush to treatment without a diagnosis of pneumonia, however, can result in inappropriate antibiotic use. Although the Centers for Medicare and Medicaid Services have used specific time cutoffs for antibiotic administration as a quality measure, the IDSA/ATS guidelines for management of pneumonia do not support the use of a specific time cutoff. The antibiotics selected should cover the likely etiologies based on clinical, laboratory, radiologic, and epidemiologic information. However, the regimen should also be as selective as possible to avoid drug toxicity, emergence of resistance to broad-spectrum agents, and excessive cost.

The prevalence of drug-resistant *S. pneumoniae* (DRSP) is increasing. In most areas of the United States, high-level penicillin resistance occurs in approximately 15 to 20% of outpatient pneumococcal sputum isolates. DRSP that is resistant to penicillin is usually resistant to other β-lactams, macrolides, tetracyclines, and trimethoprim-sulfamethoxazole (TMP-SMX). Many extended-spectrum or “respiratory” fluoroquinolones are available, such as levofloxacin, moxifloxacin, and gemifloxacin. Because oral bioavailability of fluoroquinolones is high, oral therapy provides serum and tissue levels essentially equivalent to parenteral therapy. These agents are active against DRSP and other typical or atypical pneumonia pathogens. It is not clear, however, that in vitro resistance is related to adverse clinical outcome. Most cephalosporins and macrolides achieve adequate levels in serum and tissues to successfully treat *S. pneumoniae* respiratory tract infections, even if the laboratory reports that the organism is resistant.

CA-MRSA has rapidly emerged as the most common pathogen isolated in community-acquired skin and soft tissue infections. It is also increasingly recognized as a cause of severe, rapidly progressing pneumonia with sepsis, often in children or healthy young adults with influenza. Antimicrobials with consistent in vitro activity against CA-MRSA isolates include vancomycin, TMP-SMX, daptomycin, tigecycline, linezolid, ceftaroline, and ceftobiprole. Although vancomycin is used most often for documented MRSA infections, there is concern that vancomycin may be losing efficacy in light of increasing minimum inhibitory concentrations for vancomycin. Daptomycin is inactivated by pulmonary surfactant and would not be appropriate for empiric therapy. Empirical coverage of...
MRSA should be strongly considered for patients with severe pneumonia associated with sepsis, especially those with concurrent influenza, contact with someone infected with MRSA, or radiographic evidence of necrotizing pneumonia.

Appropriate agents for outpatient treatment of adults with CAP include macrolides, doxycycline, and fluoroquinolones with enhanced activity against *S. pneumoniae* (Table 74-1). In patients properly identified at low risk for complications and who will have careful outpatient follow-up, use of a macrolide or doxycycline is reasonable. For patients at higher risk of DRSP due to recent antibiotic use or comorbidities such as chronic heart, lung, liver, or renal disease, a respiratory fluoroquinolone should be considered.

For patients who have received a fluoroquinolone within the previous few months, a combination of a macrolide plus a β-lactam agent (e.g., high-dose amoxicillin [1 g three times daily], amoxicillin-clavulanate [2 g orally twice daily], or cefpodoxime) is appropriate. Except for the administration of fluoroquinolones, these recommendations also apply to school-age children and adolescents, in whom mycoplasmal infection is common.

For patients whose illness is severe enough to require hospital admission and parenteral antibiotics, options include a combination of a β-lactam agent (e.g., ceftriaxone, cefotaxime, ampicillin-sulbactam, or ertapenem) and a macrolide (e.g., intravenous or oral azithromycin) or an extended-spectrum fluoroquinolone alone. These regimens are associated with lower mortality in elderly patients hospitalized for CAP compared with monotherapy with a third-generation cephalosporin. These regimens treat the most common bacterial pathogens, such as *S. pneumoniae, M. catarrhalis,* and *H. influenzae,* and atypical pathogens, such as *Mycoplasma, Chlamydia pneumoniae,* and *Legionella spp.* Intravenous azithromycin alone is another option, although this drug does not achieve significant serum levels and lacks significant activity against many aerobic gram-negative bacilli and DRSP. Azithromycin alone might be an appropriate choice for people with milder illness who are less likely to be bacteremic. If anaerobic organisms are suspected (e.g., aspiration), clindamycin or metronidazole could be added to the regimen, or the regimen could include an antibiotic with anaerobic activity, such as ertapenem, ampicillin-sulbactam, or piperacillin-tazobactam. Some quinolones, such as moxifloxacin, are also active against anaerobes (Table 74-2).

Seriously ill patients who present with severe sepsis or septic shock require aggressive fluid resuscitation and may benefit from more intensive management with vasopressors, transfusion, and inotropic agents as part of early goal-directed therapy. Severely ill and compromised patients are at relatively greater risk of infection due to *S. pneumoniae,* aerobic gram-negative bacilli, *S. aureus* (including MRSA), and, in some areas, *Legionella sp.* For pneumonia patients admitted to an ICU, adequate activity against DRSP may be more important. Outcomes with severe pneumococcal pneumonia may be better with combination therapy compared with a single agent such as a fluoroquinolone alone. A third-generation cephalosporin or β-lactam/β-lactamase inhibitor can be combined with a fluoroquinolone. Addition of an aminoglycoside should be considered if septic shock is present.

Patients with recent hospitalization, neutropenia, or underlying bronchiectasis are at increased risk of infection with *P. aeruginosa.* Empirical therapy should include two agents with extended gram-negative activity, including *P. aeruginosa.* Empirical regimens include cefepime, imipenem, meropenem, or piperacillin-tazobactam, plus either a ciprofloxacin (high dose) or an aminoglycoside and a macrolide. For life-threatening pneumonia in populations at risk for MRSA, and for patients recently exposed to fluoroquinolones who may have fluoroquinolone-resistant *S. pneumoniae,* consider vancomycin or linezolid. The regimen should also cover atypical pathogens and gram-negative bacilli.

Since HCAP is associated with higher mortality and a greater likelihood of unusual pathogens, it is appropriate to give broader spectrum empirical therapy, usually with a combination of antimicrobials to increase the chance that at least one antibiotic will be active against the causative pathogen. Appropriate combinations include an antipseudomonal β-lactam agent, such as piperacillin-tazobactam, cefepime, imipenem, or meropenem, with either an aminoglycoside or a fluoroquinolone and vancomycin or linezolid for MRSA.

For patients with AIDS, it is important to treat *P. jirovecii* and bacterial pathogens such as *S. pneumoniae.* TMP-SMX is the treatment of choice; the usual regimen is 20 mg/kg of TMP and 100 mg/kg of SMX daily in four divided doses, to be continued for 21 days. For most adult patients, a regimen of three ampules (80 mg of TMP and 400 mg of SMX per ampule) every 6 hours is appropriate. For patients allergic to sulfa, pentamidine can be given, 4 mg/kg over 1 hour. Toxicities of pentamidine include acute hypotension and hypoglycemia. Because pentamidine has no activity against *S. pneumoniae* or other bacterial pathogens, it is important to add a cephalosporin or other antibacterial agent to the initial regimen.

* Doses are for a 70-kg adult with normal renal and hepatic function. DRSP: drug-resistant S. pneumoniae; ICU, intensive care unit; PCP, Pneumocystis pneumonia.

empiric regimen. Other options include clindamycin, 900 mg intravenously every 8 hours, plus primaquine, 15 mg orally daily; atovaquone; trimetrexate; or TMP plus dapsone. The addition of steroids (prednisone, 40 mg orally twice daily) reduces mortality and clinical deterioration in patients with partial arterial oxygen tension (PaO2) less than 70 mm Hg or alveolar-arterial gradient greater than 35 mm Hg. Mycoplasma, Legionella, and Chlamydia spp. are uncommon etiologies of severe pneumonia in AIDS patients, so empirical therapy with erythromycin or doxycycline is not routinely recommended.

Many EDs initiate outpatient therapy in moderately ill patients, for whom hospitalization might be considered, with an initial parenteral dose of a long-acting antibiotic, such as ceftriaxone, and employ extended observation (i.e., 12–24 hours) while administering supportive care, such as hydration, antipyretics, and bronchodilators, before discharge on an oral regimen. Certain patients may also be brought back to the ED for follow-up in 24 hours and receive a second parenteral or observed oral dose of antibiotics. An extended-spectrum fluoroquinolone (oral or parenteral) is another option that may be advantageous due to additional activity against atypical pathogens and DRSP.

There is little experimental evidence that directly addresses the question of duration of therapy for pneumonia. Outpatient treatment for pneumonia is generally 10 to 14 days. A 5-day treatment course is possible with azithromycin or levofloxacin (750 mg daily).

Patients with a positive influenza antigen test or culture may benefit from antiviral treatment. Empirical antiviral treatment is reasonable with compatible clinical findings when influenza is in the community, and it may be associated with reduced mortality when started early in the course of influenza. Neuraminidase inhibitors such as oseltamivir are recommended instead of amantadine and rimantadine because they are active against influenza A and B and because many circulating strains are resistant to these older agents. Inhaled zanamivir is not recommended for patients with underlying reactive airway disease because of concern about induced bronchospasm.

**Disposition**

There is tremendous variability in physician admission decisions for pneumonia. The more common tendency is overestimation of disease severity, leading to hospitalization of patients at low risk for death or serious complications. The decision to hospitalized a patient with pneumonia does not necessarily mean that a prolonged inpatient stay is required. Observation for 12 to 24 hours in the ED or hospital may allow the early discharge of certain moderate-risk patients. Inpatient treatment of pneumonia is 15 to 20 times more expensive per patient than outpatient treatment, and most patients are more comfortable in a home environment.

Although no firm guidelines exist regarding hospital admission, a scoring system may assist with hospitalization decisions. One commonly used system is based on the Pneumonia Patient Outcomes Research Team study, a prospectively validated predictive rule for mortality among immunocompetent adults with CAP. This model (also known as the Pneumonia Severity Index [PSI]) suggests a two-step approach to assess risk. Patients in the lowest risk class who are recommended for outpatient management are those younger than age 50 years, without significant comorbid conditions (neoplasm, congestive heart failure, cerebrovascular disease, renal disease, liver disease, and HIV), and without the following findings on physical examination: altered mental status, pulse 125 beats/min or greater, respiratory rate 30 breaths/min or greater, systolic blood pressure less than 90 mm Hg, or temperature less than 35°C or 40°C or greater. Patients who do not fit the lowest risk category are classified into categories based on a scoring system that accounts for age, comorbid illness, physical examination findings, and laboratory abnormalities (Table 74-3). Hospitalization is recommended for patients with a score greater than 91, and brief admission or observation may be considered for patients with a score of 71 to 90. Although this method of assessing the likelihood of successful outpatient management is helpful, it can be cumbersome, is not modeled to predict acute life-threatening events, does not take into account dynamic evaluation over time, and has many
important exceptions (e.g., an otherwise low-risk patient with severe hypoxia would be discharged by strict interpretation of this rule). Clinical judgment should supersede a strict interpretation of this scoring system. However, a study in which physicians were educated and provided the patient’s risk score revealed a significantly lower overall admission rate, cost savings, and similar quality-of-life scores compared to those for patients conventionally managed by their physicians. Additional discharge criteria include improving and stable vital signs over a several-hour observation period, ability to take oral medications, an ambulatory pulse oximetry greater than 90%, home support, and access to follow-up. A similar tool that is easier to use is the CURB-65 rule. This rule uses only five simple criteria to determine patients at lower risk for adverse events: confusion, uremia (blood urea nitrogen >20 mg/dL), respiratory rate greater than 30, blood pressure less than 90 systolic or greater than 60 diastolic, and age 65 or greater. The risk of 30-day mortality increases with a greater number of these factors present: 0.7% with zero factors, 9.2% with two factors, and 57% with five factors. Patients with zero or one feature can receive outpatient care, those with two should be admitted, and ICU care should be considered for those with three or more. No randomized trials of hospital admission strategies directly compare the PSI to CURB-65. However, a study in which physicians were educated and provided the patient’s risk score revealed a significantly lower overall admission rate, cost savings, and similar quality-of-life scores compared to those for patients conventionally managed by their physicians. Additional discharge criteria include improving and stable vital signs over a several-hour observation period, ability to take oral medications, an ambulatory pulse oximetry greater than 90%, home support, and access to follow-up. A similar tool that is easier to use is the CURB-65 rule.

A scoring system for pneumonia mortality prediction (Table 74-3) involves assigning 1 point for every year of age, age <65 years, coma, severe hypoxia, and severe sepsis. The PSI has been validated in patients with pneumonia at the time of presentation to health care facilities, and the decision to admit a patient to the hospital largely reflects the potential for acute deterioration. Likewise, some rate of flow to ICU transfer is inevitable.

The disposition of HIV-infected patients with possible PCP is dictated by the likelihood of progression to severe disease and by the feasibility of close outpatient follow-up. Factors associated with decreased survival in AIDS patients with PCP include a history of prior PCP, anemia, hypoxemia, and medical comorbidity. Patients without multiple poor prognostic factors may be discharged from the ED with close outpatient follow-up, ideally within 2 or 3 days. Because of the potential toxicity of TMP-SMX, empirical treatment with this agent for well-appearing patients with a low probability of disease is not recommended. An empirical trial of a macrolide may be indicated for treatment of bronchitis or mild CAP in a patient at low risk for PCP (e.g., recent CD4 count >350/mm³). Any deterioration on outpatient oral antibiotics should prompt admission for a more extensive evaluation. Some clinicians initiate oral outpatient therapy with TMP-SMX or an alternate drug for patients with a high probability of PCP and favorable clinical parameters, but this should be done only if the patient can be followed closely.

The decision to admit a patient to the ICU is straightforward when patients are intubated or require vasopressors. It is more difficult to identify patients who do not require these interventions initially but may be at greater risk for deterioration and require a level of monitoring that may be beyond that available on the typical hospital ward. Objective criteria using the PSI (class V) and CURB-65 are proposed but have not been prospectively validated for the ICU admission decision. When similar criteria were retrospectively studied in a cohort of CAP patients, they did not perform better than actual physician decisions. IDSA/ATS guidelines include criteria for defining severe CAP (Table 74-4), but these have not been validated. The decision to admit a patient to the hospital largely reflects the potential for acute deterioration. Likewise, some rate of flow to ICU transfer is inevitable.

Most patients with CAP do not need respiratory isolation. Patients who could pose a threat of transmission to other patients (e.g., influenza, varicella, TB, and plague) should be isolated. People with fever and respiratory symptoms who have been traveling in an area with SARS or avian influenza should also be isolated. Neutropenic patients generally are placed in reverse isolation. HIV-infected patients who present with pneumonia should be isolated until TB can be evaluated by sputum acid-fast bacilli smears; this is particularly true for

### Table 74-4: Criteria for Severe Community-Acquired Pneumonia

- Minor criteria: 
  - Respiratory rate ≥30 breaths/min
  - Pao2/Fio2 ratio ≤250
  - Multilobar infiltrates
  - Confusion/disorientation
  - Uremia (BUN level ≥20 mg/dL)
  - Leukopenia (WBC count <4000 cells/mm³)
  - Thrombocytopenia (platelet count <100,000 cells/mm³)
  - Hypothermia (core temperature <36°C)
  - Hypotension requiring aggressive fluid resuscitation

- Major criteria:
  - Invasive mechanical ventilation
  - Septic shock with the need for vasopressors

*Other criteria to consider include hypoglycemia (in patients who do not have diabetes), acute alcoholism/alcoholic withdrawal, hyponatremia, unexplained metabolic acidosis or elevated lactate level, cirrhosis, and asplenia.

†A need for noninvasive ventilation can substitute for a respiratory rate >30 breaths/min or a Pao2/Fio2 ratio <250.

‡As a result of infection alone.

BUN, blood urea nitrogen; Pao2/Fio2, arterial oxygen pressure/fraction of inspired oxygen.

patients with other risk factors for TB. The chest radiograph cannot exclude TB in AIDS patients because it often does not have the typical appearance of TB. Isolation should be strongly considered for others at high risk for TB, such as inner-city homeless people and intravenous drug users.

**ACUTE RESPIRATORY DISTRESS SYNDROME**

Acute respiratory distress syndrome (ARDS) is a form of non-cardiogenic pulmonary edema that is a result of the nonspecific response of the lung to a variety of insults. ARDS is defined as respiratory failure indicated by a requirement for mechanical ventilation and PaO2/fraction of inspired oxygen ratio 200 or less in the appropriate clinical setting with one or more recognized risk factors. This presentation is accompanied by new, bilateral, diffuse, patchy or homogeneous pulmonary infiltrates on the chest radiograph, with no clinical evidence of heart failure, fluid overload, or chronic lung disease (pulmonary artery occlusion pressure ≤18 mm Hg).44

Respiratory failure results from damage to the region of alveolar-capillary oxygen exchange with increased permeability to plasma fluid and protein. ARDS can be caused by a direct injury to the lungs (e.g., aspiration of liquids or inhaled toxins) or may result from circulating inflammatory mediators associated with multisystem trauma, sepsis, or numerous drugs (Box 74-1). A variety of mediators are implicated in the development of ARDS, including neutrophil production of proteases and oxygen radicals, interleukins and other cytokines, tumor necrosis factor, and complement factors. This syndrome most often develops in patients already seriously ill in the hospital.

Treatment of ARDS is primarily supportive. High inspiratory pressures and positive end-expiratory pressure are often required to maintain oxygenation, so it is difficult to avoid barotrauma. Peak airway pressures should be kept at less than 35 cm H2O if possible. Outcome is improved with use of reduced tidal volumes, allowing permissive hypercapnia.45 Other ventilator techniques that may be beneficial include inverse-ratio ventilation with prolonged inspiratory time and use of a high-frequency oscillatory ventilator.46 Fluid balance must avoid increased pulmonary capillary pressure while maintaining organ perfusion. Prone positioning during ventilation may improve distribution of perfusion to ventilated lung regions, but improvement in oxygenation is variable. Inhaled nitric oxide, N-acetylcysteine, prostaglandin E1, ketoconazole, and nonsteroidal anti-inflammatory drugs produce variable results.47 Corticosteroids do not reduce mortality in early ARDS but may have benefit in the late fibroproliferative phase. Although mortality is high, most survivors recover normal or near-normal lung function. Research is focusing on preventive measures for ARDS that may be used in the ED for patients at risk. Agents under study include aerosolized surfactant, free radical scavengers, prostaglandin inhibitors, and agents that can modify interleukins and other inflammatory mediators.

### BOX 74-1

**CONDITIONS ASSOCIATED WITH ACUTE RESPIRATORY DISTRESS SYNDROME**

- Sepsis
- Shock
- Toxic gas or smoke inhalation
- Aspiration
  - Gastric contents
  - Near-drowning
  - Hydrocarbons/solvents
- Pneumonia
- Drug reaction
- Salicylates
- Opiates
- Tricyclic antidepressants
- Cyclosporine
- Amiodarone
- Cancer chemotherapeutic agents (e.g., bleomycin)
- Hydrochlorothiazide
- Trauma
- Burns
- Transfusion reaction
- Radiation injury
- Pancreatitis
- Thromboembolism
- Fat embolism
- Air embolism
- Amniotic fluid embolism
- Eclampsia
- Neurogenic (e.g., subarachnoid hemorrhage, head trauma)
- Disseminated intravascular coagulation
- High-altitude exposure
- Oxygen toxicity
- Cardiopulmonary bypass

### KEY CONCEPTS

- **Empirical antimicrobial therapy** should be started in the ED for patients admitted with pneumonia. Empirical therapy should treat the most likely pathogens, including *S. pneumoniae, H. influenzae, M. pneumonie*, and *C. pneumoniae*.
- **HIV or other immunosuppressive conditions** should be considered in all patients in whom pneumonia is suspected.
- **Communicable diseases** should be considered and isolation initiated when appropriate, including suspected TB, SARS, or influenza.
- **The disposition of patients with pneumonia** is dictated by the patient’s underlying medical conditions, the severity of illness and likelihood of clinical deterioration, and the feasibility of home care and outpatient follow-up.
- **Mycoplasma pneumonia** may present as a dense infiltrate, or pneumococcal pneumonia may present as a diffuse interstitial infiltrate.

Pleural Disease

Joshua M. Kosowsky

Pleural disease is commonly encountered in the emergency department (ED). Presentations range in severity from asymptomatic pleural effusion to tension pneumothorax. This chapter reviews the two most common nontraumatic pleural problems: spontaneous pneumothorax and pleural inflammation with effusion. Pleural space problems associated with trauma are discussed in Chapter 42, and the approach to a patient presenting with pleuritic chest pain in Chapter 17.

Perspective

Under normal conditions, the visceral and parietal pleurae lie in close apposition, with only a potential space between them. Pneumothorax is defined as the presence of free air in the intrapleural space. A spontaneous pneumothorax occurs in the absence of any external precipitating factor, either traumatic or iatrogenic. Primary spontaneous pneumothorax occurs in individuals without clinically apparent lung disease. Secondary spontaneous pneumothorax arises in the context of an underlying pulmonary disease process.

The incidence of primary spontaneous pneumothorax is approximately 15 cases per 100,000 population per year among men and 5 cases per 100,000 population per year among women. Primary spontaneous pneumothorax typically occurs in healthy young men of taller than average height. Factors associated with primary spontaneous pneumothorax include cigarette smoking and changes in ambient atmospheric pressure. Familial patterns suggest an inherited propensity in some cases of primary spontaneous pneumothorax. Mitral valve prolapse and Marfan’s syndrome are associated with spontaneous pneumothorax in the absence of clinically apparent lung disease.

Approximately one third of spontaneous pneumothoraces occur in the context of underlying pulmonary disease (Box 75-1). The incidence of secondary spontaneous pneumothorax is three times higher in men. The most common condition associated with secondary spontaneous pneumothorax is chronic obstructive pulmonary disease (COPD), which accounts for nearly 70% of cases. Patients with severe COPD (e.g., with forced expiratory volume in 1 second <1 L) are at highest risk. The incidence of spontaneous pneumothorax among patients hospitalized for emphysema is 0.8% and for asthma 0.3%.

Spontaneous pneumothorax occurs in approximately 2% of patients with acquired immunodeficiency syndrome, almost always in the setting of Pneumocystis jiroveci (previously known as Pneumocystis carinii) pneumonia. Bilateral pneumothoraces are common with P. jiroveci pneumonia, as are problems with delayed reexpansion and recurrences. Mortality in these patients is high.

Malignancy is another common etiology of secondary spontaneous pneumothorax. The occurrence of spontaneous pneumothorax in a patient with known malignancy should suggest lung metastases. In developing countries, tuberculosis and lung abscess remain leading causes of secondary spontaneous pneumothorax.

Catamenial pneumothorax is a rare condition in which recurrent spontaneous pneumothorax occurs in association with menses (typically within 72 hours of onset). Although it is termed thoracic endometriosis syndrome and often responds to ovulation-suppressing medications, the exact etiology of catamenial pneumothorax is uncertain.

Spontaneous pneumothorax is rare in childhood. The principles of diagnosis, imaging, treatment, and surgical management for pediatric primary spontaneous pneumothorax are similar to those for adult pneumothorax.

Pathophysiologic Principles

Normally, intrapleural pressure is negative (less than atmospheric), fluctuating from −10 mm Hg to −12 mm Hg during inspiration to approximately −4 mm Hg during expiration. Intrabronchial and intra-alveolar pressures are negative during inspiration (−1 to −3 mm Hg) and positive during expiration (+1 to +3 mm Hg). The alveolar walls and visceral pleura form a barrier that separates the intrapleural and intra-alveolar spaces and maintains the pressure gradient. If a defect occurs in this barrier, air enters the pleural space until either the pressures equalize or the communication seals.

With the loss of negative intrapleural pressure in one hemithorax, the ipsilateral lung collapses. A large pneumothorax results in restrictive ventilation impairment, with reduced vital capacity, functional residual capacity, and total lung capacity. Shunting of blood through nonventilated lung tissue may result in acute hypoxemia, although over time this effect is mitigated by compensatory vasoconstriction in the collapsed lung.

In tension pneumothorax, the alveolar-pleural defect acts as a one-way valve, allowing air to pass into the pleural space during inspiration and trapping it there during expiration (Fig. 75-1). This trapping leads to progressive accumulation of intrapleural air and increasingly positive intrapleural pressure,
Figure 75-1. Tension pneumothorax with total collapse of the right lung and shift of mediastinal structures to the left. Air is forced into the pleural space during expiration and cannot escape during inspiration.

Causes of Secondary Spontaneous Pneumothorax

**Airway Disease**
- Chronic obstructive pulmonary disease
- Asthma
- Cystic fibrosis

**Infections**
- Necrotizing bacterial pneumonia/lung abscess
- *Pneumocystis jiroveci* pneumonia
- Tuberculosis

**Interstitial Lung Disease**
- Sarcoidosis
- Idiopathic pulmonary fibrosis
- Lymphangiomymomatosis
- Tuberculous sclerosis
- Pneumoconioses

**Neoplasms**
- Primary lung cancers
- Pulmonary/pleural metastases

**Miscellaneous**
- Connective tissue diseases
- Pulmonary infarction
- Endometriosis/catamenial pneumothorax

Causing compression of the contralateral lung with asphyxia and worsening hypoxia. Intrapleural pressure exceeding 15 to 20 mm Hg impairs venous return to the heart. If allowed to progress, cardiovascular collapse and death ensue.

In primary spontaneous pneumothorax, disruption of the alveolar-pleural barrier occurs when a subpleural bulla (or bleb), typically located at the lung apex, ruptures into the pleural space. Subpleural bullae are found in almost all patients who undergo surgical treatment for primary spontaneous pneumothorax and are identified on computed tomography (CT) of the chest in 90% of cases. The etiology of these bullae may be related to degradation of elastic fibers within the lung and an imbalance in the protease-antiprotease and oxidant-antioxidant systems.

In the case of secondary spontaneous pneumothorax, the underlying lung disease weakens the alveolar-pleural barrier. In patients with *P. jiroveci* pneumonia, the cytotoxic effects of repeated episodes of inflammation lead to bullous and cystic changes. In patients with COPD, chronic exposure to cigarette smoke results in the development of large, thin-walled bullae that are at an increased risk for rupture. Other factors, including increased intrabronchial and intra-alveolar pressures generated by bronchospasm and coughing, also play a role.

**Clinical Features**

Symptoms of primary spontaneous pneumothorax typically begin suddenly while at rest. Ipsilateral chest pain and dyspnea are the most common symptoms. At the outset, the pain is typically “pleuritic” in nature (i.e., often described as sharp and made worse with deep inspiration), but it often evolves over time into a dull, steady ache. Although patients frequently describe shortness of breath, extreme dyspnea is uncommon in the absence of underlying lung disease or tension pneumothorax. Cough is present in a few individuals. Occasionally, patients are asymptomatic or have only nonspecific complaints. Patients may wait several days before they seek medical attention, and a significant number delay presentation for 1 week or more. Without treatment, symptoms often resolve spontaneously within 24 to 72 hours, although the pneumothorax is still present.

Physical findings tend to correlate with the degree of symptoms. A mild sinus tachycardia is the most common physical finding. With a large pneumothorax, decreased or absent breath sounds with hyperresonance to percussion may be present. Other classic signs include unilateral enlargement of the hemithorax, decreased excursion with respirations, absent tactile fremitus, and inferior displacement of the liver or spleen. Absence of any or all of these findings does not exclude pneumothorax, however, and a chest radiograph should be obtained when pneumothorax is suspected.

With tension pneumothorax, signs of asphyxia and decreased cardiac output develop. Tachycardia (often >120 beats/min) and hypoxia are common. Hypotension is a late and ominous finding. Distention of the jugular veins is common but may be difficult to detect. Displacement of the trachea to the contralateral side is classically described but is an uncommon finding, usually occurring only in the immediately preterminal phase of the pneumothorax, if at all. Its absence should not be considered evidence that a tension phenomenon is not present.

In patients with significant underlying lung disease, pneumothorax presents differently. Because of poor pulmonary reserve, dyspnea is nearly universal, even when the pneumothorax is small, and symptoms tend not to resolve on their own. Physical findings, such as hyperexpansion and distant breath sounds, often overlap considerably with the underlying lung disease, making the clinical diagnosis difficult. For this reason, the diagnosis of pneumothorax should be considered whenever a patient with COPD presents with an exacerbation of dyspnea.

Although suggested by the patient’s history and physical examination, the diagnosis of pneumothorax is generally made with the chest radiograph. The classic radiographic appearance is that of a thin, visceral pleural line lying parallel to the chest wall, separated by a radiolucent band devoid of lung markings. The average width of this band can be used to estimate the size of the pneumothorax with a fair degree of accuracy (Fig. 75-2), but in general, it is more reasonable simply to characterize the pneumothorax as small, moderate, large, or total. The estimated size of the pneumothorax and the patient’s clinical status can be useful in guiding management decisions.

Tension pneumothorax is a clinical diagnosis, and delaying treatment to obtain radiographic confirmation is inadvisable. When the diagnosis of tension pneumothorax is not apparent clinically and a chest radiograph is obtained, the classic appearance is one of complete lung collapse with gross distention of the thoracic cavity on the affected side and shift of mediastinal
Figure 75-2. Determining the size of a pneumothorax. Calculation of average interpleural distance to predict pneumothorax size. PA, posteroanterior.

Figure 75-3. Radiograph of tension pneumothorax with mediastinal shift to left.

structures across the midline (Fig. 75-3). In patients with underlying pulmonary disease, however, pleural adhesions and lack of lung elasticity may mask the fact that a pneumothorax is under significant positive pressure.

When pneumothorax is suspected but not seen on a standard chest radiograph, an expiratory film may be obtained. Theoretically, the volumes of the lungs and the chest cavity are reduced during expiration so that the relative size of the pneumothorax is enhanced. Although occasionally helpful in identifying a small apical pneumothorax, routine use of expiratory films does not improve diagnostic yield. In critically ill patients for whom only a supine chest radiograph can be obtained, the finding of a “deep sulcus” (i.e., a deep lateral costophrenic angle) can suggest the presence of pneumothorax on that side (see Fig. 75-3).

Special care should be taken when viewing the chest radiographs of patients with underlying lung disease. In patients with COPD, the relative paucity of lung markings makes pneumothorax more difficult to detect. At the same time, giant bullae may simulate the radiographic appearance of pneumothorax. A clue to differentiating a pneumothorax from a giant bulla is that the former tends to run parallel to the chest wall, whereas the latter tends to have a more concave appearance.

When the diagnosis is unclear, computed tomography (CT) can differentiate between the two entities. While CT is considered the gold standard for the diagnosis of pneumothorax, it requires that patients be stable enough for transport. Bedside ultrasound is also a rapid and accurate diagnostic aid. Assessment for pneumothorax begins over the upper anterior chest wall in the midclavicular line and proceeds inferolaterally toward the anterior axillary line. Once the pleural line is identified, the presence of lung sliding during respiration effectively rules out a pneumothorax in the area being scanned. The differential diagnosis of pneumothorax includes numerous conditions associated with chest pain and dyspnea. Among the most important of these is pulmonary embolism, which may present in similar fashion with unilateral pleuritic chest pain. Most pleural-based processes (pneumonia, embolism, tumor) have characteristic radiographic findings. Rarely, pneumothorax may mimic an acute myocardial infarction with electrocardiogram changes simulating an acute injury pattern.

Spontaneous pneumomediastinum is a closely related clinical entity, diagnosed by the presence of subcutaneous emphysema and the finding of mediastinal air on chest radiography. In contrast to spontaneous pneumothorax, spontaneous pneumomediastinum typically occurs during exertion, particularly after a strenuous Valsalva maneuver. Most cases of spontaneous pneumomediastinum occur in the absence of known underlying disease and have a benign course. Secondary causes of pneumomediastinum (e.g., Boerhaave’s syndrome) are more serious, and treatment is aimed at the underlying disorder.

Spontaneous hemopneumothorax is a rare but potentially serious condition that occurs when collapse of the lung is associated with rupture of a vessel in a parietopleural adhesion. The clinical presentation is similar to that of spontaneous pneumothorax but may be accompanied by symptoms and signs of hemorrhagic shock. Treatment entails large-caliber tube thoracostomy to evacuate the pleural space, reexpand the lung, and tamponade bleeding.

Pneumothorax has a readily available, highly reliable confirmatory diagnostic test (i.e., chest radiography). Absence of a pneumothorax on chest radiography should prompt a search for an alternate diagnosis.
Management

Whether in the field or in the ED, if the clinical circumstances suggest tension pneumothorax, treatment should not be delayed by awaiting further cardiovascular compromise or definitive diagnosis by chest radiography. As soon as tension pneumothorax is believed to be present, the pleural space should be decompressed. This decompression may be accomplished by insertion of an intravenous catheter or by immediate tube thoracostomy, depending on the availability of equipment and the expertise of the providers. The diagnosis is confirmed by the hiss of air escaping under positive pressure as the needle or chest tube enters the pleural space. Needle decompression is only a temporizing procedure, and definitive management requires prompt tube thoracostomy. In morbidly obese patients, the needle and catheter may be of insufficient length to reach the pleural space, and a longer needle may be required.

The management of spontaneous pneumothorax has two goals: (1) to evacuate air from the pleural space, and (2) to prevent recurrence. Pursuit of the latter goal extends well beyond the realm of the ED but may influence the initial approach to management. Therapeutic options for treatment of pneumothorax range from simple observation or aspiration with a catheter to video-assisted thoracoscopic surgery or thoracotomy. Decisions must be individualized and consider several factors, including size of the pneumothorax, severity of signs, presence of underlying pulmonary disease, other comorbidities, history of previous pneumothoraces, patient reliability, degree and persistence of the air leak, and available follow-up monitoring.

For otherwise healthy, young patients with a small primary spontaneous pneumothorax (i.e., <20% of the hemithorax), observation alone may be appropriate. The intrinsic reabsorption rate ranges from 1 to 2% per day, a rate that is accelerated by a factor of 4 with the administration of 100% oxygen. By lowering the alveolar partial pressure of nitrogen, supplemental oxygen increases the rate at which air diffuses across the pleural-alveolar barrier. The disposition of patients managed noninterventionally for a small pneumothorax varies by institution. Most physicians admit these patients for at least 6 hours of observation, often in an ED-based observation unit. A repeat chest radiograph can be obtained before discharge to document that there is no increase in the size of the pneumothorax. Discharged patients should be able to obtain emergency medical services quickly and should have definitive follow-up evaluation in 24 hours. Air travel and underwater diving must be avoided until the pneumothorax has completely resolved. Unreliable patients are not candidates for this approach.

For primary spontaneous pneumothoraces that are larger in size (i.e., ≥20% of the hemithorax), aspiration with an intravenous catheter may be attempted. If 6 hours after aspiration the chest radiograph shows no reaccumulation of the pneumothorax, the catheter is removed, and the patient can be discharged home, with the same caveats that apply to patients managed with observation alone.

Although there is no universal agreement on the optimal treatment of patients presenting with a first episode of primary spontaneous pneumothorax, data suggest that aspiration may be equally effective as chest tube drainage. Advantages of simple aspiration include low morbidity, lack of invasiveness, and overall cost savings, with reported rates of successful outcome ranging from 45 to 71%. Success is less likely when the patient is older than 50 years or the volume of air aspirated exceeds 2.5 L, suggesting a continuing air leak. If aspiration fails to reexpand the lung fully, the catheter can be attached to a water-seal device or to a one-way Heimlich valve and managed like a small-caliber chest tube.

Most secondary spontaneous pneumothoraces should be managed with tube thoracostomy because less invasive approaches (i.e., observation or simple aspiration) are associated with significantly lower success rates. Similarly, patients who present with respiratory distress, have tension pneumothorax, or are likely to require mechanical ventilation should undergo tube thoracostomy to reexpand the lung definitively. Also, if there is detectable pleural fluid (hemothorax or hydrothorax), tube thoracostomy is required. Finally, tube thoracostomy may be considered in uncomplicated cases of primary spontaneous pneumothorax either as a first-line intervention or after a less invasive approach (i.e., observation or simple aspiration) fails.

For most primary spontaneous pneumothoraces, placement of a small-caliber (7–14F) tube is generally sufficient because air leakage tends to be minimal. Small-caliber tubes are easy to insert, are well tolerated by patients, and leave only a small scar after removal. Complications associated with small-caliber tubes include kinking, malposition, inadvertent removal, occlusion by pleural fluid or clotted blood, and large persistent air leaks. For secondary spontaneous pneumothorax, a standard size (20–28F) thoracostomy tube is recommended. When there is detectable pleural fluid or an anticipated need for mechanical ventilation, a larger tube size (≥28F) is required.

After insertion, the tube is attached to a water-seal device and left in place until the lung has reexpanded fully and the air leak has ceased. A Heimlich valve, which consists of a one-way flutter valve covered in transparent plastic, can be used in place of a water-seal device and allows unhindered ambulation. Specific complications associated with the use of a Heimlich valve include accidental disconnection and occlusion by fluid.

Routine application of suction neither increases the rate at which the lung reexpands nor improves patient outcome and is no longer recommended after standard tube thoracostomy. Rather, the use of suction (with a pressure of 20 cm H2O) is reserved for situations in which the lung fails to reexpand after drainage through a water-seal device or Heimlich valve for 24 to 48 hours.

In most cases, chest tube management requires hospital admission, although outpatient management of spontaneous pneumothorax with a small-caliber tube and Heimlich device is described. Common complications of chest tube placement include incorrect placement, pleural infection, and prolonged pain. Reexpansion pulmonary edema and reexpansion hypotension are rare occurrences after rapid evacuation of large pneumothoraces.

Outcome

Most spontaneous pneumothoraces resolve within 7 days of tube thoracostomy. Air leaks that persist for longer than 2 days are less likely to resolve on their own. If an air leak persists beyond 4 to 7 days, tube thoracostomy is considered to have failed, and surgical intervention generally is recommended.

Failure of tube thoracostomy is more common with secondary spontaneous pneumothoraces because these tend to be associated with larger and more persistent air leaks. In the setting of COPD, healing of the alveolar-pleural barrier may be impaired by chronic inflammatory changes and loss of vascularity in pulmonary tissue. The success rate also decreases substantially with recurrent episodes of pneumothorax, declining from 91% for treatment of a first pneumothorax to
52% for treatment of a first recurrence and to 15% for treatment of a second recurrence.25

Recurrences of spontaneous pneumothorax are common. The risk of recurrence after a primary spontaneous pneumothorax is approximately one in three, with studies reporting rates between 16 and 50%.26 Younger age, lower weight-to-height ratio, and history of smoking are associated with an increased rate of recurrence. Recurrence rates after a secondary spontaneous pneumothorax are slightly higher (39–47%).6

Recurrences may be life-threatening for patients with serious underlying lung disease, and intervention is advocated to prevent recurrence as part of the initial approach to secondary spontaneous pneumothorax. In contrast, for patients with primary spontaneous pneumothorax, interventions typically are not considered until after a second ipsilateral pneumothorax. Preventive treatment also is recommended for patients who plan to continue activities such as flying or diving that increase the risk of serious complications if a pneumothorax recurs. CT can be used in primary spontaneous pneumothorax to detect emphysematous changes, predict the likelihood of recurrence, and guide intervention decisions.27

A variety of operative and nonoperative interventions prevent recurrences. One strategy promotes adherence of parietal and visceral pleura, which obliterates the pleural space. Pleurodesis can be accomplished by mechanical pleural abrasion or by instillation of sclerosing agents. Another strategy involves resection of apical bullae or other lesions at risk for causing recurrences. Often the two strategies are combined. Minimally invasive procedures, such as video-assisted thoracoscopic surgery, allow for resection of bullae and pleurodesis.28 Patients with extensive bullae may require thoracotomy for wider visualization of lesions. Success rates are generally good, ranging from 86 to 100%.

**PLEURAL INFLAMMATION AND EFFUSION**

**Perspective**

Under normal circumstances, a thin layer of fluid lies between the visceral and the parietal pleurae, which obliterates the pleural space. Pleuritis can be accomplished by mechanical pleural abrasion or by instillation of sclerosing agents. Another strategy involves resection of apical bullae or other lesions at risk for causing recurrences. Often the two strategies are combined. Minimally invasive procedures, such as video-assisted thoracoscopic surgery, allow for resection of bullae and pleurodesis.28 Patients with extensive bullae may require thoracotomy for wider visualization of lesions. Success rates are generally good, ranging from 86 to 100%.

A pleural effusion associated with bacterial pneumonia, bronchiectasis, or lung abscess is called a *parapneumonic effusion*. The term *complicated parapneumonic effusion* refers to parapneumonic effusions that require tube thoracostomy for their resolution. Empyema (or pus in the pleural space) requires the presence of bacteria on Gram’s staining of the pleural fluid.

Fluid anatomically confined and not freely flowing in the pleural space is termed a *loculated effusion*. Loculated effusions occur when there are adhesions between the visceral and the parietal pleurae. Hemothorax and chylothorax (i.e., from rupture of the thoracic duct) are special instances of pleural effusion that are approached separately.

**Pathophysiologic Principles**

Pleural fluid is produced from systemic capillaries at the parietal pleural surface and absorbed into pulmonary capillaries at the visceral pleural surface. Lymphatics also play an important role in removing pleural fluid. Movement of fluid across the pleural surfaces is governed by Starling’s law. Under normal circumstances, the direction of pleural fluid flow is largely governed by the difference in hydrostatic pressure between the systemic and the pulmonary circulations (Fig. 75-4). Pleural fluid exists in a dynamic equilibrium in which influx equals efflux, with approximately 1 L of fluid traversing the pleural space in 24 hours. Under normal conditions, the amount of fluid that remains in the pleural space is small (~0.1–0.2 mL/kg body weight) and clinically or radiographically undetectable. Pleural effusion develops whenever influx of fluid into the pleural space exceeds efflux. Numerous disorders can lead to formation of a pleural effusion. Pleural effusions classically are

BOX 75-2  CAUSES OF PLEURAL EFFUSION

Transudates
- Congestive heart failure
- Cirrhosis with ascites
- Nephrotic syndrome
- Hypoalbuminemia
- Myxedema
- Peritoneal dialysis
- Glomerulonephritis
- Superior vena cava obstruction
- Pulmonary embolism

Exudates
- Infections
  - Bacterial pneumonia
  - Bronchiectasis
  - Lung abscess
  - Tuberculosis
  - Viral illness
  - Neoplasms
- Primary lung cancer
- Mesothelioma
- Pulmonary/pleural metastases
- Lymphoma

Connective Tissue Disease
- Rheumatoid arthritis
- Systemic lupus erythematosus

Abdominal/Gastrointestinal Disorders
- Pancreatitis
- Subphrenic abscess
- Esophageal rupture
- Abdominal surgery

Miscellaneous
- Pulmonary infarction
- Uremia
- Drug reactions
- Postpartum
- Chylothorax

Causes of pleural effusion are divided into two groups—transudates and exudates—according to the composition of the pleural fluid (Box 75-2).

Transudates are essentially ultrafiltrates of plasma, containing very little protein. A transudative effusion develops when there is an increase in the hydrostatic pressure or decrease in the oncotic pressure within pleural microvessels. The primary cause of increased hydrostatic pressure is congestive heart failure, which is responsible for about 90% of transudative effusions. In hepatic cirrhosis and nephrotic syndrome, increased hydrostatic pressure is combined with loss of plasma oncotic pressure because of significant decreases in serum albumin. Patients with severe malnutrition may develop transudative effusions resulting from severe isolated hypoalbuminemia.

Exudates contain relatively high amounts of protein, reflecting an abnormality of the pleura itself. An exudative effusion is the result of increased membrane permeability or defective lymphatic drainage. Any pulmonary or pleural process associated with inflammation can result in an exudative effusion. In the absence of clinically apparent effusion, pleuritic symptoms may still be present. The most common form of exudative effusion is a parapneumonic effusion, in which infection of the adjacent lung elicits an intense inflammatory response in pleura, disrupting normal membrane permeability. Malignant effusions are the second most common form of exudative effusion and often reflect alterations in pleural permeability and problems with lymphatic drainage. Exudative effusions also may arise in response to inflammatory abdominal processes, such as pancreatitis or subphrenic abscess, presumably owing to altered permeability of the diaphragm itself. Exudative effusions may be reabsorbed or organize into fibrous tissue, resulting in pleural adhesions.

Some pleural effusions can present as either transudates or exudates or may have characteristics of both. In the case of pulmonary embolism, the pathogenesis of pleural effusion is often multifactorial, reflecting increased pulmonary vascular pressure (a transudative process) and ischemia and breakdown of the pleural membrane (an exudative process).

Massive effusions (>1.5–2 L) are most commonly associated with malignancy but also can arise in the setting of congestive heart failure, cirrhosis, and other conditions. Massive effusions may restrict respiratory movement, compress the lungs, and result in intrapulmonary shunting. In extremely rare cases, tension hydrothorax can develop, with mediastinal shift and circulatory embarrassment.

Clinical Features

Symptoms associated with pleural effusion are most often due to the underlying disease process and not the effusion itself. Small pleural effusions can be entirely asymptomatic. A new pleural effusion may be heralded by localized pain or pain referred to the shoulder. Viral pleuritis and pulmonary infarction commonly are associated with pleuritic chest pain. When the volume of pleural fluid reaches 500 mL, dyspnea on exertion or at rest may occur as a result of compromised pulmonary function.

The patient's history often helps to establish the diagnosis for pleural effusion or pleural inflammation. A history of congestive heart failure, liver disease, uremia, or malignancy can direct subsequent evaluation. The pain of viral pleuritis usually is preceded by several days of a typical viral prodrome, with low-grade fever, sore throat, and other upper respiratory or constitutional symptoms. In the absence of such prodromal symptoms, an alternate etiology for pleuritis such as pulmonary embolism must be sought.

Physical findings depend on the size of the effusion but are often either dominated or obscured by the underlying disease process. Classic physical signs of pleural effusion include diminished breath sounds, dullness to percussion, decreased tactile fremitus, and occasionally a localized pleural friction rub. The simple technique of auscultatory percussion (i.e., percussing the chest while listening for a dullness with the stethoscope) may be even more sensitive and specific for the physical diagnosis of pleural effusion. Egophony and enhanced breath sounds can often be appreciated at the superior border of the effusion because of underlying atelectatic lung tissue. In the setting of pleuritis, a pleural friction rub may be appreciated. With massive effusions, signs of mediastinal shift may be present.

Chest radiography confirms the clinical suspicion of pleural effusion and occasionally reveals a pleural effusion as an incidental finding. The classic radiographic appearance of a pleural effusion is blunting of the costophrenic angle on the upright chest radiograph. On a frontal (anteroposterior or posteroanterior) projection, a volume of 250 to 500 mL of pleural fluid is required before radiographic demonstration is possible. A lesser amount of fluid may be visible in the posterior costophrenic gutter on a lateral projection. With larger effusions, the hemidiaphragm is obscured, and an upwardly concave
meniscus may be seen because pleural fluid has a tendency to layer higher laterally than centrally. Pleural fluid can extend up a major fissure and appear as a homogeneous density in the lower two thirds of the lung field. Massive pleural effusion can appear as a totally opacified hemithorax.

In the recumbent patient, free pleural fluid gravitates superiorly, laterally, and posteriorly and may not be clearly discernible on a supine radiograph. If the effusion is large enough, diffuse haziness or partial opacification of a hemithorax may be seen. Other findings on the supine radiograph may include apical capping, obliteration of the hemidiaphragm, and a widened minor fissure. The radiographic appearance of pleural effusions can be confusing. Subpulmonic effusions (fluid collections between the lung base and the diaphragm) can be difficult to diagnose, often simulating an elevated hemidiaphragm. Clues to the presence of a subpulmonic effusion include shifting of the apparent dome of the diaphragm toward the lateral chest wall and, when located on the left side, an increase in the distance between the gastric bubble and aerated lung. Fluid that loculates in a fissure may take on a fusiform appearance and can simulate a mass (Fig. 75-5). Such “fluid pseudotumors” are common in patients with congestive heart failure.

Other imaging techniques, such as ultrasound and CT, may be helpful in localizing effusions and characterizing underlying lung processes. Ultrasound is particularly helpful, because it can be used to guide thoracentesis and decrease the risk of complications, particularly in the case of small or loculated effusions. Sonographically, pleural effusion is demonstrated by the appearance of hypoechoic fluid located above the diaphragm with loss of the usual mirror-image artifact. Pleural effusions smaller than 500 mL, however, can be missed with bedside radiography.

Pulmonary embolism is the most commonly overlooked disorder in the workup of a pleural effusion, and any patient with an undiagnosed pleural effusion should be evaluated for possible pulmonary embolism. Pleural effusion resulting from pulmonary embolism usually occupies less than one third of the hemithorax, but dyspnea is frequently out of proportion to size.

An unexplained pleural effusion requires further investigation. Unless required to rule out an immediately life-threatening condition such as empyema or hemothorax, pleural fluid evaluation may be deferred to an inpatient or outpatient setting. The primary goal of pleural fluid analysis is to distinguish between transudative and exudative effusions. The presence of a transudate suggests an underlying process (e.g., congestive heart failure, nephrotic syndrome), whereas the presence of an exudate mandates a more extensive diagnostic evaluation. Although numerous alternative measurements are proposed, Light’s criteria remain a widely accepted means of differentiating transudates and exudates (Box 75-3).

In the presence of an exudative effusion, additional pleural fluid analyses further classify the effusion. A pleural fluid pH of less than 7.3 is associated with parapneumonic effusions, malignancies, rheumatoid effusions, tuberculosis, and systemic acidosis. A pH of less than 7.0 strongly suggests empyema (or esophageal rupture). A pleural fluid pH of less than 7.0 and glucose less than 50 mg/dL are reasonable indications for tube thoracostomy.

Normal pleural fluid contains less than 1000 white blood cells/mm³; exudative pleural fluid may contain over 10,000 white blood cells/mm³. Although the absolute cell count has limited diagnostic value, a predominance of neutrophils suggests an acute process, such as pneumonia, pulmonary embolus, or acute tuberculous pleuritis. A predominance of monocytes or lymphocytes suggests a more chronic process, such as malignancy or established tuberculosis. Pleural fluid from any patient with an undiagnosed exudative pleural effusion should undergo Gram’s staining and culture for bacteria (aerobic and anaerobic), mycobacteria, and fungi.
In the absence of a traumatic tap, bloody fluid suggests trauma, neoplasm, or pulmonary infarction. If the hematocrit of the pleural fluid is more than 50% that of the peripheral blood, the effusion is, by definition, a hemothorax. Atraumatic hemothorax is relatively rare but can occur with spontaneous rupture of a tumor or blood vessel (e.g., ruptured aortic aneurysm).

If the diagnosis of a malignant pleural effusion is being considered, pleural fluid should be submitted for cytologic examination. Contrary to popular perception, the sensitivity for diagnosis of pleural malignancy does not depend on the volume of pleural fluid extracted during thoracentesis. Cyto-

Management

In patients with large effusions, urgent therapeutic thoracentesis may stabilize respiratory or circulatory status. The presence of empyema mandates insertion of a chest tube to drain the pleural space adequately and prevent the development of loculations. If an effusion is already located, streptokinase or urokinase can be injected by a thoracic surgeon, pulmonolo-
gist, or interventional radiologist into the pleural space in an attempt to dissolve adhesions and allow fluid to drain freely. Hemothorax requires tube thoracostomy to evacuate the pleural space, quantify bleeding, and allow apposition of the two pleural surfaces to tamponade hemorrhage. If bleeding exceeds 200 mL/hr, thoracotomy should be considered.

In most other cases, the decision to proceed with therapeutic thoracentesis in the ED can be individualized. For example, therapeutic thoracentesis may be considered in patients with known, recurrent malignant effusion, in whom symptomatic relief may permit discharge.

Pain relief is an important consideration in the management of patients with pleuritis, which may have a significant inflammatory component. Nonsteroidal anti-inflammatory drugs are relatively successful in treating pleural pain. Opioid analgesia is safe and effective, but care should be exercised in debili-
tated patients or patients with severe lung disease because of potential respiratory depression.

Relative contraindications to thoracentesis include coagu-

Outcome

Some pleural effusions reflect little clinical significance. For example, small pleural effusions are common after abdominal surgery and in the postpartum state and resolve spontaneously within a few days. Effusions associated with viral pleuritis are generally self-limited and resolve without specific treatment.

For patients with congestive heart failure, pleural effusions generally respond well to diuretic therapy. If an effusion persists despite several days of aggressive diuresis, a diagnostic thoracentesis should be considered.

Pleural effusions associated with malignancy are a significant cause of morbidity in patients with advanced cancer. The presence of a malignant effusion indicates disseminated disease, and most of the malignancies that cause pleural effu-
sions—mainly lung or breast carcinoma and lymphoma—are not curable by this stage. Therapeutic thoracentesis can relieve dyspnea in the short term, but malignant effusions tend to be recurrent, often rapidly so. Management strategies include chemical or mechanical pleurodesis to obliterate the pleural space or placement of a pleuroperitoneal shunt to provide continual drainage. Control of pleural effusions can improve quality of life in these patients.

Parapneumonic effusions contribute significantly to the morbidity and mortality of pneumonia. Therefore, the presence of a parapneumonic effusion may influence the decision to hospitalize a patient with community-acquired pneumo-

Acute coronary syndrome (ACS) refers to the constellation of clinical diseases occurring as a result of acute myocardial ischemia. ACS includes a spectrum of clinical presentations ranging from unstable angina (UA) to non-ST segment elevation myocardial infarction (NSTEMI) and ST segment elevation myocardial infarction (STEMI). ACS and in particular acute myocardial infarction (AMI) remain the leading cause of death in much of the developed world. Tremendous progress, however, is occurring in the diagnosis and management of ACS.

■ HISTORICAL PERSPECTIVE

Several advances in the mid-twentieth century drastically changed the approach to acute coronary care. The development of external defibrillators and cardiac pacemakers, as well as new pharmacologic agents, provided physicians with an effective approach for treating life-threatening dysrhythmias. The introduction of selective coronary arteriography by Sones in 1959 revolutionized the management of patients with coronary artery disease (CAD). In 1960, Kouwenhoven inaugurated the era of cardiopulmonary resuscitation (CPR).

These developments led to the recognition that the time between onset of symptoms and the initiation of therapy is critical. Day organized a cardiac arrest team in 1960 and established the first coronary care unit 2 years later, reducing AMI mortality by half. In the 1980s, DeWood and colleagues performed coronary angiography early in the course of AMI and demonstrated coronary occlusion in the infarct-related artery. The early experience of Rentrop with the intracoronary administration of streptokinase in AMI ushered in the era of fibrinolytic therapy.

Recognition that the majority of sudden deaths from ischemic heart disease occur outside the hospital led to numerous advances for preadmission ACS care. In 1969, advanced prehospital cardiac care was initiated in Belfast with Pantridge’s mobile cardiac care units. In 1970, Nagel and coworkers reported the benefits of preadmission telemetry for field advanced cardiac life support in patients experiencing dysrhythmias or sudden cardiac death. In the 1980s, portable 12-lead electrocardiograms (ECGs) were introduced into the emergency medical systems environment.

Although the ECG is the cornerstone for the diagnostic evaluation of ACS, diagnostic tools such as echocardiography, stress testing, nuclear imaging, and computed tomography (CT) play increasingly important roles, particularly when the diagnosis is not straightforward.

Fibrinolytic therapy and interventional, catheter-based techniques revolutionized the treatment of patients with STEMI during the 1980s. Combination therapies with antiplatelet, antithrombotic, and fibrinolytic agents continue to be studied for STEMI patients. Interventional success is improving with the use of newer stenting devices and glycoprotein platelet inhibitors. Current efforts focus on the establishment of regional cardiac centers, expansion of interventional capabilities to smaller hospitals, and the development of STEMI systems of care.

■ EPIDEMIOLOGY

Ischemic heart disease and CAD continue to be the leading causes of death among adults in many developed countries. Ischemic heart disease accounts for nearly 1 million deaths in the United States annually, of which approximately 160,000 occur in persons 65 years of age or younger. More than half of all deaths from cardiovascular disease occur in women, and CAD remains a major cause of morbidity and mortality in women beyond their middle to late fifties. The incidence of cardiovascular disease is expected to continue to increase due to lifestyle and behavioral changes that promote heart disease.

A significant reduction in age-adjusted mortality from CAD has occurred in the United States over the past four decades. In large part, the decline is accompanied by diminished mortality from AMI. This is due to a reduction in the incidence of AMI by 25% and a sharp drop in the case-fatality rate. Reduction in cigarette smoking, management of lipids, and improved management of hypertension and diabetes mellitus undoubtedly play a role, along with significant advances in medical treatment.

In 2005, 5.8 million patients were evaluated for chest pain or related complaints in the emergency department (ED) in the United States, comprising 5% of all ED visits that year. In 2004, 4.1 million visits to the ED had a primary diagnosis of cardiovascular disease and over 1.5 million patients were hospitalized for a primary or secondary diagnosis of ACS. In addition, approximately 2% of patients with ACS are discharged from the ED. In the United States, approximately 900,000 persons suffer an AMI, of whom 20% die before reaching the hospital, and 30% die within 30 days. The majority of fatalities from CAD occur outside the hospital, usually from an ACS-related dysrhythmia within 2 hours of onset of...
symptoms. For many patients who suffer a nonfatal AMI, their lives are limited by an impaired functional status, anginal symptoms, and a diminished quality of life. The economic cost for the evaluation and care of patients with an ACS is estimated to be $100 to $120 billion annually.10

■ SPECTRUM OF DISEASE

ACS includes the spectrum from asymptomatic CAD and stable angina to UA, AMI, and sudden cardiac death.

Stable Angina

Stable angina pectoris is transient, episodic chest discomfort resulting from myocardial ischemia. This discomfort is typically predictable and reproducible, with the frequency of attacks constant over time. Physical or psychological stress (physical exertion, emotional stress, anemia, dysrhythmias, or environmental exposures) may provoke an attack of angina that resolves spontaneously over a constant, predictable period of time with rest or nitroglycerin (NTG).

The Canadian Cardiovascular Society classification for angina is defined as follows: class I, no angina with ordinary physical activity; class II, slight limitation of normal activity as angina occurs with walking, climbing stairs, or emotional stress; class III, severe limitation of ordinary physical activity as angina occurs on walking one or two blocks on a level surface or climbing one flight of stairs in normal conditions; and class IV, inability to carry on any physical activity without discomfort as anginal symptoms occur at rest.

Unstable Angina

Unstable angina is broadly defined as angina occurring with minimal exertion or at rest, new-onset angina, or a worsening change in a previously stable anginal syndrome in terms of frequency or duration of attacks, resistance to previously effective medications, or provocation with decreasing levels of exertion or stress. Rest angina is defined as angina occurring at rest, lasting longer than 20 minutes, and occurring within 1 week of presentation. New-onset angina is angina of at least class II severity with onset within the last 2 months. Increasing or progressive angina is diagnosed when a previously known angina becomes more frequent, longer in duration, or increased by one class within the last 2 months of at least class III severity. Symptoms that last longer than 20 minutes despite cessation of activity are consistent with angina at rest and indicate the diagnosis of UA.

UA is often referred to as preinfarction angina, accelerating or crescendo angina, intermediate coronary syndrome, and preocclusive syndrome, underscoring its difference from stable angina. UA should be considered a possible harbinger of AMI and hence should be treated aggressively. A patient with a diagnosis of angina in the ED should be presumed to have UA until a thorough clinical evaluation reliably determines otherwise.

UA can also be defined from a pathophysiologic perspective. Plaque rupture accompanied by thrombus formation and vaso-spasm illustrate the intracoronary events of UA. This is frequently characterized by an electrocardiographic abnormality, including T wave and ST segment changes.

Variant angina—also known as Prinzmetal’s angina—is caused by coronary artery vasospasm at rest with minimal fixed coronary artery lesions; it may be relieved by exercise or NTG. The ECG reveals ST segment elevation that is impossible to discern from AMI electrocardiographically and, at times, clinically.

Acute Myocardial Infarction

AMI is defined as myocardial cell death and necrosis of the myocardium. The four-decade-old World Health Organization (WHO) definition for AMI has been replaced by clinical criteria developed jointly by the European Society for Cardiology and American College of Cardiology (ACC) that focus on defining infarction as any evidence of myocardial necrosis. This definition for an acute, evolving, or recent MI requires a typical rise and fall of a cardiac biochemical marker, serum troponin, with clinical symptoms, ECG changes, or coronary artery abnormalities based on interventional evaluation.11 The actual definition11 includes the following: either one of these criteria satisfies the diagnosis for an acute, evolving, or recent MI:

1. Typical rise and gradual fall (troponin) or more rapid rise and fall (isoenzyme of creatine kinase with muscle and brain subunits [CK-MB]) of biochemical markers of myocardial necrosis with at least one of the following:
   a. Ischemic symptoms;
   b. Development of pathologic Q waves on the ECG;
   c. ECG changes indicative of ischemia (T wave changes or ST segment elevation or depression); and/or
   d. Coronary artery intervention.
2. Pathologic findings of an AMI.

Any one of the following criteria11 satisfies the diagnosis for established MI:

1. Development of new pathologic Q waves on serial ECGs. The patient may or may not remember previous symptoms. Biochemical markers of myocardial necrosis may have normalized, depending on the length of time since the infarct developed; or
2. Pathologic findings of a healed or healing MI.

AMI is further classified by findings on the ECG at presentation, as either ST elevation MI (STEMI) or non-ST elevation MI (NSTEMI). Previous descriptors such as transmural and non-transmural, as well as Q wave and non-Q wave MI fail to adequately describe the coronary event and its related pathophysiology, electrocardiographic presentation, and pathologic outcome. The differentiation between STEMI and NSTEMI has important implications in terms of management, therapeutic intervention, outcome, and prognosis for patients with AMI. In fact, the American College of Cardiology and American Heart Association have developed separate clinical guidelines for the management of patients with UA/NSTEMI and those patients with STEMI.6,7,12

■ PATHOPHYSIOLOGY

The underlying pathophysiology of ACS is myocardial ischemia as a result of inadequate perfusion to meet myocardial oxygen demand. Myocardial oxygen consumption is determined by heart rate, afterload, contractility, and wall tension. Inadequate perfusion most commonly results from coronary arterial vessel stenosis as a result of atherosclerotic CAD. Usually, the reduction of coronary blood flow does not cause ischemic symptoms at rest until the vessel stenosis exceeds 95%. Myocardial ischemia, however, may occur with exercise and increased myocardial oxygen consumption when there is as little as 60% vessel stenosis.11

CAD is characterized by thickening and obstruction of the coronary vessel arterial lumen by atherosclerotic plaques. Although atherosclerosis is usually diffuse and multifocal, indi-
individual plaques vary greatly in composition. Fibrous plaques are considered stable but can produce anginal symptoms with exercise and increased myocardial oxygen consumption because of the reduction in coronary artery blood flow through the fixed, stenotic lesions. Vulnerable or unstable fibrolipid plaques consist of a lipid-rich core separated from the arterial lumen by a fibromuscular cap. These lesions are likely to rupture, resulting in a cascade of inflammatory events, thrombus formation, and platelet aggregation that can cause acute obstruction of the arterial lumen and myocardial necrosis.14

Thrombus formation is considered an integral factor in ACS, including UA, NSTEMI, and STEMI. All of these syndromes are initiated by endothelial damage and atherosclerotic plaque disruption, which leads to platelet activation and thrombus formation. Platelets play a major role in the thrombotic response to rupture of coronary artery plaque and subsequent ACS. Platelet-rich thrombi are also more resistant to fibrinolysis than fibrin- and erythrocyte-rich thrombi. The resulting thrombus can occlude the vessel lumen, leading to myocardial ischemia, hypoxia, acidosis, and eventually infarction. The consequences of the occlusion depend on the extent of the thrombotic process, the characteristics of the preexisting plaque, the extent of the vessel obstruction, and the availability of collateral circulation.

In the setting of UA, acute stenosis of the vessel is noted; complete obstruction, however, is encountered in only 20% of cases. In these cases, it is likely that extensive collateral vessel circulation prevents total cessation of blood flow, averting frank infarction.13,15 With AMI, the occlusive fibrin-rich thrombus is fixed and persistent, resulting in myonecrosis of the cardiac tissue supplied by the affected artery. Angiographic studies demonstrate that the preceding coronary plaque lesion is often less than 50% stenotic, indicating that the most important factors in the infarction are the acute events of plaque rupture, platelet activation, and thrombus formation rather than the severity of the underlying coronary artery stenosis.

Another important aspect of ACS is vasospasm. After significant coronary vessel occlusion, local mediators and vasoactive substances are released, inducing vasospasm, which further compromises blood flow. Central and sympathetic nervous system input increases within minutes of the occlusion, resulting in vasomotor hyperreactivity and coronary vasospasm. Sympathetic stimulation by endogenous hormones such as epinephrine and serotonin may also result in increased platelet aggregation and neutrophil-mediated vasoconstriction. Approximately 10% of MIs occur as a result of coronary artery spasm and subsequent thrombus formation without significant underlying CAD. This mechanism may be more prevalent during UA and other coronary syndromes that do not result in infarction.

Further myocardial injury occurs at the cellular level as inflammatory, thrombotic, and other debris from the occlusive plaque lesion are released and embolize into the distal vessel. Such embolization can result in obstruction at the microvasculature, leading to hypoperfusion and ischemia of the distal myocardial tissue, even after reopening of the more proximal, initial, obstructing lesion. In particular, the introduction of calcium, oxygen, and cellular elements into ischemic myocardial tissue can lead to irreversible myocardial damage that causes reperfusion injury, prolonged ventricular dysfunction (known as myocardial stunning), or reperfusion dysrhythmias. Neutrophils probably play an important role in reperfusion injury, occluding capillary lumens, decreasing blood flow, accelerating the inflammatory response, and resulting in the production of chemoattractants, proteolytic enzymes, and reactive oxygen species.

### CLINICAL FEATURES

#### Preadmission Evaluation

Appropriate pharmacotherapy for persistent anginal chest pain in the preadmission setting includes sublingual NTG, oral aspirin (acetylsalicylic acid [ASA]) that is preferably chewed, and intravenous morphine sulfate; the acronym MONA summarizes preadmission pharmacotherapeutic interventions (morphine, oxygen, nitroglycerin, and aspirin). Establishment of the diagnosis of ACS in this setting is difficult, however, as chest pain is a poor predictor of the diagnosis and adjunctive tools are limited.16 Preadmission 12-lead ECG offers high specificity (99%) and positive predictive value (93%) for AMI in patients with atraumatic chest pain while increasing the paramedic scene time by an average of only 3 minutes. This approach offers the advantages of earlier detection of STEMI and more rapid reperfusion therapy.2,7 Preadmission 12-lead ECG would be necessary in the limited populations in whom preadmission fibrinolytic therapy might be applicable, such as those with prolonged out-of-hospital times (>90–120 minutes).17

#### Emergency Department Evaluation

#### The History

The character of the chest discomfort as well as the onset, location, radiation, duration, prior presence, and any exacerbating or alleviating factors should be sought. Associated symptoms, especially of a cardiac, pulmonary, gastrointestinal, and neurologic nature, should be elicited. Results from any prior cardiac testing should be obtained.

Traditionally, a history of risk factors for CAD is sought; these include male gender, age, tobacco smoking, hypertension, diabetes mellitus, hyperlipidemia, family history, artificial or early menopause, and cocaine abuse. Approximately 80% of a population of more than 122,000 patients with known CAD had at least one of the four conventional risk factors (diabetes mellitus, cigarette smoking, hypertension, or hyperlipidemia).16 Cardiac risk factor burden has little impact on the ED diagnosis of ACS; however, in patients greater than 40 years of age, ACS is 22 times more likely if four of the five major risk factors (diabetes mellitus, smoking, hypertension, hyperlipidemia, and family history) are present (compared to none).18 Nevertheless, Bayesian analysis indicates that risk factors are a populational phenomenon and do not increase or decrease the likelihood of any condition in any one patient. Thus, the presence of an individual risk factor, or a collection of risk factors, is far less important in diagnosing acute cardiac ischemia in the ED than the history of presenting illness, the presence of ST segment or T wave changes, or cardiac marker abnormalities.20

Risk assessment tools, such as the PURSUIT (The Platelet Glycoprotein IIb-IIIa in Unstable Angina: Receptor Suppression Using Integrilin Therapy) risk model, the GRACE (Global Registry of Acute Coronary Events) risk model, and the TIMI (Thrombosis in Myocardial Infarction) risk score, can be used to determine risk of death and ischemia in NSTEMI and STEMI. These may aid in decision making and in risk stratifying patients so as to properly disposition them (telemetry bed vs. intensive care unit). The TIMI risk score assigns a point each for seven factors based on history, cardiac markers, and the ECG. It can be accessed at www.timi.org.9

There are several nontraditional risk factors for coronary disease. Antiphospholipid syndrome, rheumatoid arthritis, and particularly systemic lupus erythematosus (SLE) are each associated with a higher risk of cardiovascular disease.21 Women
with SLE 35 to 44 years of age are over 50 times more likely to have an MI than a similar age- and gender-matched Framingham population.22

The Classic History

The term angina refers to “tightening,” not pain. Classic angina pectoris may not be pain at all but rather a “discomfort,” with a “squeezing,” “pressure,” “tightness,” “fullness,” “heaviness,” or “burning” sensation. Classically, it is substernal or precordial in location and may radiate to the neck, jaw, shoulders, or arms. If the discomfort does extend down the arm, it classically involves the ulnar aspect. Discomfort in the left chest and radiation to left-sided structures is typical, but location and radiation to both sides or to only the right side may be consistent with angina. Radiation of the discomfort to the right arm or shoulder, or to both arms or shoulders, exceeds radiation to the left arm or shoulder in terms of likelihood of the chest pain being due to ACS, although all exceeded a positive likelihood ratio of 2.23 Further, classic features of angina pectoris include exacerbation with exertion, a heavy meal, stress, or cold and alleviation by rest. The onset of pain at rest in no way excludes the diagnosis of angina. Anginal discomfort characteristically lasts from 2 to 5 minutes up to 20 minutes, and it is rare for it to last only a few seconds or to endure for hours or incessantly, “all day” (Table 76-1).

Symptoms characterized associated with angina pectoris, of other entities of ACS, include the following: dyspnea, nausea, vomiting, diaphoresis, weakness, dizziness, excessive fatigue, or anxiety (Table 76-2). If these symptoms arise, either alone or in combination, as a presenting pattern of known ischemic coronary disease, they are termed anginal equivalent symptoms. Recognition that coronary ischemia may arise with an anginal equivalent, rather than a classic symptom is the key to understanding the atypical presentation of ACS. Complaints of “gas,” “indigestion,” or “heartburn” in the absence of a known history of gastroesophageal reflux disease or reproducible pain upon abdominal palpation should raise suspicion of ACS, and similarly if the heartburn is different from the patient’s usual gastroesophageal reflux.

The Atypical History

A description of typical symptoms (crushing, retrosternal chest pain or pressure) is often lacking in ACS; this may be due to atypical features of the pain (e.g., character, location, duration, exacerbating and alleviating factors) or the presence of anginal equivalent symptoms (e.g., dyspnea, nausea, vomiting, diaphoresis, indigestion, syncope). Patients with an ultimate diagnosis of AMI or UA can have pain that is pleuritic, positional, or reproduced by palpation.24 Some patients describe their pain as burning or indigestion, sharp, or stabbing (see Table 76-2).

In a large study of nearly 435,000 patients ultimately diagnosed with AMI, one third did not have chest pain on presentation.26 Multiple studies have identified risk factors for atypical presentation of ACS: diabetes mellitus, older age, female gender, nonwhite ethnicity, dementia, no prior history of MI or hypercholesterolemia, no family history of coronary disease, and previous history of congestive heart failure (CHF) or stroke.26–31 In patients with AMI or UA, atypical presenting complaints include dyspnea, nausea, diaphoresis, syncope, or pain in the arms, epigastrum, shoulder, or neck.

Atypical features of ACS are present with increasing frequency in sequentially older populations. Before age 85, chest pain is found in the majority of patients with acute MI, although dyspnea, stroke, weakness, and altered mental status are notably present. In those older than 85 years, however, atypical symptoms are more common than chest pain, with 60 to 70% of patients older than 85 presenting with an anginal equivalent complaint, especially dyspnea.28–30 Coincident ACS is more likely to occur in the elderly; patients who present with another acute condition (e.g., trauma, infection) should be scrutinized for concurrent ACS.32

Patients with diabetes mellitus are at heightened risk for ACS as well as an atypical presentation such as dyspnea, nausea or vomiting, confusion, or fatigue. Medically unrecognized AMI can occur in 40% of patients with diabetes mellitus compared with 25% of a nondiabetic population, and myocardial scar unaccompanied by antemortem diagnosis of MI is three times more likely in diabetics.33

As with age and diabetes, female gender is an important risk factor for MI without chest pain.34 In some series, less than 60% of women reported chest discomfort at the time of their MI, with others reporting dyspnea, indigestion, or vague symptoms such as weakness, unusual fatigue, cold sweats, sleep disturbance, anxiety, or dizziness.34,35

Finally, nonwhite racial and ethnic populations may have atypical symptoms in ACS.26 Compelling data demonstrate a disparity in treatment approach related to race in patients with acute manifestations of coronary heart disease.35 Whether this is related to the atypical nature of presenting symptoms in different racial groups is not clear. Although certain features of the chest pain history serve to increase or decrease the likelihood of ACS, none of them is strong enough to endorse discharge of the patient based on the history alone.23

Physical Examination

The physical examination focuses on the cardiac, pulmonary, abdominal, and neurologic examinations, looking for signs of severe illness in patients with symptoms of ACS as well as other entities in the differential diagnosis of chest pain and the anginal equivalent syndromes (Table 76-3). Altered mental status, diaphoresis, and signs of CHF are all ominous findings in patients presenting with symptoms consistent with ACS. Historical studies using untrained physicians identified chest wall tenderness or “reproducible” chest wall tenderness in up to 15% of patients ultimately diagnosed with AMI, but these data are highly suspect. The real incidence of truly reproducible chest wall tenderness (i.e., when the patient reliably identifies to the examiner that the pain produced on palpation is

identical to the pain causing the patient’s presentation) in ACS is probably vanishingly small. It has been suggested that chest pain that is fully pleuritic, positional, or reproducible by palpation (the three P’s) is at low risk (yet not no risk) for ACS.23

Outcomes in Atypical Presentations

Not surprisingly, atypical presentation of patients with ACS is linked to delay in diagnosis and poorer outcomes.27 In the Second National Registry of Myocardial Infarction (NRMI-2) study, patients with MI presenting without chest pain were significantly more likely to die in the hospital (23 vs. 9% for patients with chest pain) and were more likely to experience stroke, hypotension, or heart failure that required intervention, possibly reflecting the older age and greater comorbidity in this group.26 Patients with atypical symptomatology present for medical care later and are less likely to receive aspirin, beta-adrenergic blockers, heparin, fibrinolysis, and emergent reperfusion therapy.26 Patients 65 years of age or less with NSTEMI have a 1% chance of dying during their hospitalization, but this risk is increased to 10% for patients ages 85 years and up.32

Missed Diagnosis of Acute Coronary Syndrome

Approximately 2 to 4% of patients with acute MI who present to the ED are discharged without diagnosis.38 The highest mean payments for emergency physician medical malpractice claims are related to this population of patients. Atypical presenting symptoms are an obvious causative consideration. Patients with undiagnosed ACS discharged from the ED are significantly younger, more likely to be women or nonwhite, more likely to have atypical complaints, and less likely to have ECG evidence of acute ischemia.36–40 Among all patients with cardiac ischemia, women younger than 55 years seem to be at highest risk for inappropriate discharge. With respect to ECG findings, 53% of patients with missed AMI and 62% of patients with missed UA have normal or nondiagnostic ECGs. In one

Patients with undiagnosed ACS discharged from the ED are significantly younger, more likely to be women or nonwhite, more likely to have atypical complaints, and less likely to have ECG evidence of acute ischemia.36–40 Among all patients with cardiac ischemia, women younger than 55 years seem to be at highest risk for inappropriate discharge. With respect to ECG findings, 53% of patients with missed AMI and 62% of patients with missed UA have normal or nondiagnostic ECGs. In one
series, the emergency physician failed to detect ST segment elevations of 1 to 2 mm in 11% of the MI patients. Finally, the risk-adjusted mortality ratio for all patients with acute cardiac ischemia is 1.9 times higher among nonhospitalized patients. Factors associated with misdiagnosis of ACS in medical malpractice closed claims analysis include physicians with less ED experience who document histories less clearly, admit fewer patients, and misinterpret the ECG.

Early Complications of Acute Myocardial Infarction

Bradydysrhythmias and atrioventricular (AV) conduction block occur in 25 to 30% of patients with AMI; sinus bradycardia is most commonly seen. Symptomatic bradydysrhythmias in the first few hours following inferior AMI tend to be atroventricular responsive; conduction abnormalities that appear beyond 24 hours of MI tend not to respond to atropine. Patients with AV block in the setting of anterior AMI tend to respond poorly to therapy and have a poor prognosis.

Tachydysrhythmias are quite common in the setting of AMI and may be atrial in origin (e.g., sinus tachycardia and atrial fibrillation) or ventricular (e.g., ventricular tachycardia and fibrillation). Not all require treatment, such as a compensatory sinus tachycardia in patients with AMI complicated by CHF. Primary ventricular fibrillation occurs in an estimated 4 to 5% of patients with AMI, with 60% of these cases occurring in the first 4 hours and 80% within 12 hours.

Cardiogenic shock is hypotension with end-organ hypoperfusion resulting from decreased cardiac output that is unresponsive to restoration of adequate preload. Patients at risk include those with large infarcts, prior MI, low ejection fraction on presentation (<35%), older age, and diabetes mellitus. Although some differential diagnoses can usually be reasonably excluded (e.g., sepsis, anaphylaxis, adrenal crisis, and hypovolemic or hemorrhagic states), other causes of shock with similar presentations should be considered, such as aortic dissection, pulmonary embolism, pericardial tamponade, and ventricular free wall rupture accompanying acute MI. Adjunctive diagnostic measures include bedside echocardiography and invasive hemodynamic monitoring, with the latter demonstrating systemic hypotension, low cardiac output, elevated filling pressures, and increased systemic vascular resistance. Therapeutic measures include vasopressor and inotropic support, intraaortic balloon counterpulsation, and early revascularization; fibrinolytic therapy does not decrease mortality in cardiogenic shock.

Left ventricular free wall rupture is uncommon. Approximately one third of cases occur in the first 24 hours, and the remainder occur 3 to 5 days after transmural MI. Clinically, free wall rupture may occur with sudden death, pulseless electrical activity, or precipitous decline in the presence of AMI. Subacute presentations include agitation, chest discomfort, and repetitive vomiting. Signs of pericardial effusion on the ECG or echocardiogram are suggestive of the diagnosis in the setting of acute or recent MI. Free wall rupture is almost universally fatal, although prompt diagnosis followed by emergent surgical intervention may rarely be lifesaving; pericardiocentesis is indicated as an immediate temporizing intervention.

Rupture of the interventricular septum may also occur; it may arise similarly to cardiogenic shock and free wall rupture of the ventricle. The clue to this diagnosis on physical examination is the development of a new, harsh, loud holosystolic murmur heard best at the left lower sternal border. The diagnosis can be confirmed by echocardiography with color flow Doppler imaging. The presentation of acute, catastrophic deterioration with a new, harsh systolic murmur should prompt immediate cardiac surgery consultation for repair of a septal defect or ruptured papillary muscle of the mitral valve. Medical therapy including vasopressor and inotropic support, as well as intra-aortic balloon counterpulsation, is an important bridge to the definitive surgical treatments of valve repair or replacement.

Pericarditis, when associated with AMI, can occur early or in a delayed fashion; the former is termed infarct pericarditis, and the latter is known as post-MI syndrome or Dressler’s syndrome. Infarct pericarditis is associated with transmural insult and thus principally involves the pinnacles of the infarct zone near the epicardium. Although the characteristic ST segment changes may be obscured by ST segment abnormalities related to the infarction itself, if they are evident, they are logically quite localized. Infarct pericarditis is a common cause of new chest pain in the first week after MI. This pain is characteristically pleuritic and worse in the supine position. Embolic complications are more common in patients with infarct pericarditis; linked to this is the higher rate of ventricular aneurysm development in this population.

Dressler’s syndrome, unlike infarct pericarditis, does not require transmural involvement. It is a relatively uncommon, late complication occurring from 1 week to several months after the MI. Clinical features include fever, malaise, pleuropericardial pain, and at times the presence of a rub on cardiac auscultation. Laboratory findings are highly nonspecific and include an elevated sedimentation rate and leukocyte count. The ECG may show ST segment-T wave findings of pericarditis, although as with infarct pericarditis, these changes may be overshadowed by the evolving changes of the recent MI. PR segment depression is a telltale clue. Pericardial or pleural effusions may be evident and can be serous or bloody. Echocardiography assesses pericardial fluid and risk of tamponade. The pericardial reaction is believed to be immune mediated, and treatment includes anti-inflammatory agents.

Stroke may also complicate AMI, most commonly ischemic or thromboembolic. The major predisposing mechanisms with a recent MI are embolization from left ventricular mural thrombus with decreased ejection fraction, embolization from the left atrial appendage with atrial fibrillation, and hypercoagulability with concomitant carotid arterial disease. The rate of stroke is higher in the setting of MI (0.9% tapering to 0.1% at day 28 after MI) than in control subjects (0.014%).

Hemorrhagic stroke is an obvious concern in the patient receiving fibrinolytic therapy. The rate of hemorrhagic stroke with varying fibrinolytic agents is under 1%, although the rate climbs in older patients. Percutaneous coronary intervention (PCI) lowers the overall risk of stroke compared with fibrinolytic therapy. Analysis of only fibrinolytic-eligible patients from the NRMI-2 database yields more than 24,000 patients treated with alteplase and more than 4000 who received primary angioplasty. The difference in stroke rate is highly significant (1.6% in the fibrinolytic group vs. 0.7% in the angioplasty group). Considering hemorrhagic strokes, the difference is again dramatic (1.0% in the fibrinolytic group vs. 0.1% in the angioplasty group).

Hyperglycemia in the setting of AMI may be viewed as a complication, as well as a complicating disease process in AMI. Hyperglycemia is present in up to one half of all patients with STEMI, yet only one fifth to one fourth of those patients are recognized diabetics. Elevated glucose at the time of admission has independent negative implications for mortality rates in AMI patients. Although fasting blood sugar the day after presentation is a better predictor, an admission blood glucose greater than 200 mg/dL is linked to similar mortality rates among diabetics and nondiabetics. There is a 4% mortality increase for nondiabetic patients for every 18 mg/dL elevation in blood glucose level. Hyperglycemia seems to induce a
complex set of unfavorable cellular and biochemical circumstances, including negative effects on coronary flow and microvascular perfusion, as well as adverse effects on platelet function, fibrinolysis, and coagulation. Intravenous insulin therapy for glucose normalization is linked to improved outcomes in patients with STEMI as well as those in the medical intensive care unit. ACC/AHA guidelines acknowledge that tight control of blood glucose during and after STEMI decreases acute and 1-year mortality rates.47

### DIAGNOSTIC INVESTIGATIONS

#### Electrocardiography

In patients with ACS, the ECG assesses the evolution of the syndrome and the response to treatment. The ECG is analyzed for signs of ST segment elevation AMI, evidence of cardiac ischemia, determination of cardiac rhythm, and possible evidence of a noncardiac cause of the chief complaint (e.g., in pulmonary embolism, pericarditis).

The ECG in ACS may manifest dynamic changes. Morphologic changes may occur in the T wave, the ST segment, the QRS complex, and even in the PR segment (e.g., ST segment depression in atrial infarction or infarct-related pericarditis). A variety of rhythm disturbances are also possible. Notably, the ECG may be normal or nonspecifically abnormal in the presence of ACS, including AMI. The ECG is limited by individual variations in coronary anatomy, preexisting coronary disease (e.g., previous MI, collateral circulation, coronary bypass surgery) and by the fact that it does not view the posterior, lateral, and apical left ventricular walls particularly well.44

Thus, a single ECG must be evaluated in context. It is neither 100% sensitive nor 100% specific for AMI and reflects a single point in time. In addition, overreliance on a normal or nonspecifically abnormal ECG in a patient with anginal chest pain who is currently sensation free should be avoided. Patients with an initially nondiagnostic ECG who later develop AMI during that hospitalization more often are sensation free or with an initially nondiagnostic ECG who later develop AMI who is currently sensation free should be avoided. Patients who are currently sensation free or with waxing and waning symptoms should demonstrate some fluctuation in the degree of ST segment deviation in the presence of ACS.

ST segment elevation, both benign and pathologic, is common (see Table 76-4). Most normal ECGs, especially those of men, may have some degree of ST segment elevation—indeed, upward of 90%. This elevation is seen in the precordial leads and it is usually 1 mm or more in men and 1 mm or less in women. The ST segment elevation is concave and is more prominent the deeper the corresponding S wave. Because of the common occurrence of this finding, it is not a normal variant but rather a normal finding.31–34 A helpful point in differentiating normal ST segment elevation from the pathologic ST segment elevation of AMI is that the latter is a dynamic phenomenon; ECGs recorded sequentially over time with waxing and waning symptoms should demonstrate some fluctuation in the degree of ST segment deviation in the presence of ACS.

**ST segment depression** is generally considered to represent subendocardial or noninfarction ischemia. In addition, ST segment depression in ACS (1) may be seen in non-ST segment elevation AMI, (2) may precede ST segment elevation in ST segment elevation AMI, (3) may reflect a “mirror image” of ST segment elevation from posterior MI when found in the right-sided precordial leads (i.e., ST segment depression in V1 to V3 in posterior MI), and (4) may represent reciprocal ST segment depression seen with ST segment elevation AMI. With *reciprocal ST segment depression*, such changes are seen in leads on the “opposite” side of the heart from simultaneous ST segment elevation. Inferior MI with ST segment elevation more frequently manifests reciprocal ST segment depression than does its anterior counterpart. The reciprocal ST segment depression in inferior MI is best seen in lead aVL, which is 150 degrees removed from lead III when considering the positive poles of these leads in the frontal plane. Anterior ST segment elevation AMI may feature reciprocal ST segment depression in at least one of the inferior leads (II, III, or aVF). The ST segment depression seen in leads V1 to V3 with posterior MI is actually a reciprocal change from the ST segment elevation that would be recorded in

The earliest electrocardiographic finding in AMI is the hyperacute T wave, which maintains its vector but becomes tall and peaked within minutes of the interruption of blood flow. It is usually broad based and slightly asymmetrical. The hyperacute T wave progresses to ST segment elevation in classic MI. This hyperacuity may be missed on the initial ECG. The differential diagnosis of the tall T wave includes hyperacute T waves of ischemia, hyperkalemia, benign early repolarization (BER), left ventricular hypertrophy (LVH), left bundle branch block (LBBB), and pericarditis (Fig. 76-1).

As the AMI progresses, ST segment elevation may become evident. Morphologic variations of ST segment elevation can be seen from the J (or junction) point at the end of the QRS complex to the apex of the T wave. This upsloping portion of the ST segment usually progresses as it elevates from flat to convex or domed; if flat, it is characteristically horizontally or obliquely so. At times, the ST segment may be concave or scooped in its elevation with AMI45; this morphology may progress to a convex shape or may stay the same throughout the infarction. The concave morphology, if noted in all elevated ST segments, is atypical for AMI and more commonly seen with other ST segment elevation syndromes (Table 76-4 and Fig. 76-2).50,51

ST segment elevation is measured in millimeters; one block on the ECG tracing is equivalent to 1 mm in height. The baseline is usually considered to be the TP segment, although some clinicians advocate using the terminal point of the PR segment. In general, the most definable, constant baseline evident on the ECG should be used.

ST segment elevation, both benign and pathologic, is common (see Table 76-4). Most normal ECGs, especially those of men, may have some degree of ST segment elevation—indeed, upward of 90%. This elevation is seen in the precordial leads and it is usually 1 mm or more in men and 1 mm or less in women. The ST segment elevation is concave and is more prominent the deeper the corresponding S wave. Because of the common occurrence of this finding, it is not a normal variant but rather a normal finding.31–34 A helpful point in differentiating normal ST segment elevation from the pathologic ST segment elevation of AMI is that the latter is a dynamic phenomenon; ECGs recorded sequentially over time with waxing and waning symptoms should demonstrate some fluctuation in the degree of ST segment deviation in the presence of ACS.

ST segment depression is generally considered to represent subendocardial or noninfarction ischemia. In addition, ST segment depression in ACS (1) may be seen in non-ST segment elevation AMI, (2) may precede ST segment elevation in ST segment elevation AMI, (3) may reflect a “mirror image” of ST segment elevation from posterior MI when found in the right-sided precordial leads (i.e., ST segment depression in V1 to V3 in posterior MI), and (4) may represent reciprocal ST segment depression seen with ST segment elevation AMI. With reciprocal ST segment depression, such changes are seen in leads on the “opposite” side of the heart from simultaneous ST segment elevation. Inferior MI with ST segment elevation more frequently manifests reciprocal ST segment depression than does its anterior counterpart. The reciprocal ST segment depression in inferior MI is best seen in lead aVL, which is 150 degrees removed from lead III when considering the positive poles of these leads in the frontal plane. Anterior ST segment elevation AMI may feature reciprocal ST segment depression in at least one of the inferior leads (II, III, or aVF). The ST segment depression seen in leads V1 to V3 with posterior MI is actually a reciprocal change from the ST segment elevation that would be recorded in
Figure 76-1. Hyperacute T wave of acute myocardial infarction. A, Note the broad, tall T waves in leads V3 and V4 in this patient with chest pain and diaphoresis. These are the hyperacute T waves of early ST segment elevation myocardial infarction. The ST segment is just beginning to rise in leads V3 and V4; leads V1 and V2 are also suspicious. B, This tracing is from the same patient, roughly 30 minutes after the electrocardiogram in A. Note the prominent ST segment elevation in leads V1 to V4.

Figure 76-2. Analysis of ST segment–T wave morphology in acute myocardial infarction (AMI), benign early repolarization (BER), and acute pericarditis. An analysis of the ST segment–T wave morphology (from the beginning at the J point to the end at the apex of the T wave) may be particularly helpful in distinguishing among the various causes of ST segment elevation (STE) and identifying the AMI case. A, The initial upsloping portion of the ST segment is usually either flat (horizontally or obliquely) or convex in the patient with AMI. This morphologic observation, however, should be used only as a guideline; it is not infallible. B, Non-AMI causes of STE are seen here with concavity of the ST segment–T wave (left BER, middle pericarditis, right BER). C, Patients with STE related to AMI may demonstrate concavity of this portion of the waveform.
posterior leads V8 and V9, were they to be employed. Reciprocal changes in the setting of STEMI increase the specificity and positive predictive value of the ECG in AMI.52,53

Ischemic ST segment depression is typically horizontal or downsloping; an upsloping contour may be seen but is less frequently associated with ischemia. Subendocardial ischemic ST segment depression may be diffuse, spanning anterior and inferior leads. The differential diagnosis of ST segment depression includes myocardial ischemia or infarction, repolarization abnormality of ventricular hypertrophy (the “strain” pattern), bundle branch block, ventricular paced rhythm, digoxin effect, hyperkalemia, hypokalemia, pulmonary embolism, intracranial hemorrhage, myocarditis, rate-related ST segment depression, postcardioversion of tachydyssrhythmias, and pneumothorax (Fig. 76-3).

T wave inversions, although extremely nonspecific, should suggest possible myocardial ischemia. Normally, the T wave is upright in the left-sided leads I, II, and V3 to V6 and inverted in the right-sided lead aVR. T wave vectors are variable in leads III, aVL, and aVF. They are usually normally inverted in V1 and are occasionally normally inverted in lead V2. The T wave inversions of ACS are classically narrow and symmetrically inverted. The preceding ST segment is typically isoelectric and may be bowed slightly upward or concave. Associated ST segment depression may occur. T wave inversions are best viewed in comparison with the most recent prior ECG, given the multitude of normal variations (Fig. 76-4).

A notable subgroup of ischemic T wave inversions is associated with Wellens’ syndrome, which classically manifests either deep symmetrical T wave inversions or biphasic T wave changes in the anterior precordial leads. The presence of biphasic T waves is suggestive of ischemic heart disease. Other electrocardiographic features include isoelectric or minimally elevated (<1 mm) ST segments and no precordial Q waves. This finding may manifest in the anginal or pain-free state and may or may not be accompanied by cardiac enzyme elevations, which is indicative of a lesion of the left anterior descending artery.

Although T wave inversion is sought as a harbinger of ACS, it can also occur as an evolutionary change after MI. In MI without culprit artery reperfusion, as the ST segments return to baseline, the T waves may invert, although not particularly deeply. In hearts that have been reperfused, T wave inversion may follow ST segment elevation, in either a biphasic or deeply inverted morphology, appearing much like the T wave changes of Wellens’ syndrome.53,56

The clinician must also consider pseudonormalization of the T wave as a potential electrocardiographic indicator of ACS. Pseudonormalization occurs when, during an acute episode of chest discomfort or anginal equivalent, an apparently normal-appearing T wave on the ECG has replaced the “normally
inverted T wave that existed prior to the development of symptoms. The T wave has assumed a normal appearance and may indicate ACS at this presentation.

The differential diagnosis of T wave inversion is broad and includes ACS, ventricular hypertrophy, bundle branch block, ventricular paced rhythm, myocarditis, pericarditis, pulmonary embolism, pneumothorax, Wolff-Parkinson-White syndrome, cerebrovascular accident, hypokalemia, gastrointestinal disorders, hyperventilation, persistent juvenile T wave pattern, and normal variants.

Q waves are generally representative of irreversible myocardial necrosis but are rarely the sole manifestation of AMI. Pathologic Q waves may emerge within the first hour of infarction, but most commonly develop 8 to 12 hours into the infarction. It follows that ST segment elevation with concomitant Q waves does not preclude consideration of emergent reperfusion therapy. Q waves may persist after MI as enduring markers of previous infarction on the ECG; in some cases, however, Q waves disappear with time regardless of whether the infarcted territory was reperfused.

Anatomic Location of Acute Myocardial Infarction

The regional distribution of an AMI can be derived from noting the pattern of the various morphologic changes that are described (Table 76-5). Anterior infarctions are primarily evidenced by changes in the precordial leads V1 to V4 (Fig. 76-5).

Regional ST segment elevation is evident in leads V1 to V4 to include leads V5, V6, I, and aVL. In anterior ST segment elevation AMI, reciprocal ST segment depression may occur in leads III and aVF. The anterior wall is served by the left anterior descending artery. The first diagonal branch of the left anterior descending artery is likely to be involved when the ST segment elevation extends to leads I and aVL. Isolated occlusion of the diagonal branch of the left anterior descending artery displays similar findings, but of smaller amplitude, to those seen with left anterior descending artery occlusion (ST segment elevation in leads V2 and V3, and possibly leads V1 and/or V4, along with ST segment depression in lead II and either III, aVF, or both).57

Lateral infarctions are frequently seen in concert with anterior infarction (anterolateral), inferior infarctions (inferolateral), or inferior infarctions with posterior extension (inferoposterolateral). This is due to the fact that the lateral wall of the heart is variably served by the left anterior descending, right coronary, and left circumflex coronary arteries. Thus, lateral involvement is manifested by changes in some or all of the lateral leads I, aVL, V5, and V6. So-called high lateral infarctions are restricted to leads I and aVL (Fig. 76-6) and are suggestive of occlusion of the left circumflex coronary artery; ST segment elevation in these leads may be accompanied by reciprocal ST segment depression in leads III, aVF, and V1. Based on cardiac magnetic resonance imaging localization of some of these lesions, new Q waves appearing in leads I and aVL (but not V6) indicate a “mid-anterior wall MI,” previously referred to as a “high lateral MI.”6

Inferior infarctions are characterized by morphologic changes in limb leads II, III, and aVF. The inferior wall of the heart and the AV node are served by the right coronary artery in roughly 90% of cases (right dominant); in the remainder, the left circumflex artery serves that function (left dominant). An inferior ST segment elevation AMI is present if two or more contiguous inferior leads (III, aVF, II) are involved; reciprocal ST segment depression is frequently seen in lead aVL, lead I, or both (Fig. 76-7) and perhaps in the anterior precordial leads: V1 less than V2 and V3. ST segment depression in leads V1 to V3 in the presence of inferior MI can be due to reciprocal change, to posterior extension, or to simultaneous anterior ischemia during inferior infarction. ST segment elevation inferiorly that is greater in lead III than in lead II, accompanied by ST segment depression in lead aVL, I, or both, is 90% sensitive and 71% specific for right coronary artery occlusion.44 ST segment elevation in lead V1 in the presence of an ST segment elevation inferior MI (with elevation greater in lead

Figure 76-5. Anterior wall acute myocardial infarction (AMI). ST segment elevation is evident in leads V1 to V4. The morphology seems obliquely straight. Emergency cardiac catheterization revealed a 90% stenotic lesion in the left anterior descending artery; the patient did well after placement of a coronary stent but showed serum marker evidence of AMI.
Chapter 76 / Acute Coronary Syndrome

Figure 76-6. Anterolateral acute myocardial infarction. ST segment elevation is seen in leads I, aVL, V5, and V6. A proximal left anterior descending artery lesion with thrombus was noted at emergent percutaneous coronary intervention.

Figure 76-7. Inferior acute myocardial infarction with reciprocal changes. Marked ST segment elevation is seen inferiorly (leads II, III, and aVF). Classic reciprocal ST segment depression is evident in leads I and aVL.

III than in lead II) suggests concomitant right ventricular infarction. Coexistent reciprocal change with inferior STEMI is associated with larger infarct size and increased mortality. Occlusion of the left circumflex artery may be occult on the 12-lead ECG. If it is responsible for inferior ST segment elevation, expect the ST segment elevation in lead III not to be greater than that seen in lead II, and lead aVL may display an isoelectric or elevated ST segment.44

Posterior infarctions as isolated infarctions are estimated to contribute to 15 to 20% of all AMIs and are usually seen along with inferior or inferolateral infarctions. Posterior infarctions occur in isolation in about 4% of AMI cases (demonstrating elevated ST segments only in accessory leads V7 through V9).6

The culprit lesion may be in the right coronary artery, its posterior descending branch, or the left circumflex artery. In that the 12-lead ECG features no electrodes placed directly over the posterior wall of the heart, one must infer acute STEMI of the posterior wall from what are actually reciprocal ST segment changes in the right precordial leads (V1 to V3). Findings include (1) horizontal ST segment depression; (2) a tall, upright T wave; (3) a tall, wide R wave; and (4) an R wave amplitude/S wave amplitude ratio greater than 1 (Fig. 76-8). The combination of horizontal ST segment depression with an upright T wave increases the diagnostic accuracy of the 12-lead ECG for posterior MI. In that the tall R wave in the right precordial leads is actually the mirror image of a posterior Q wave, its emergence may be delayed in posterior infarction. Additional leads (posterior leads V8 and V9) increase the sensitivity for detection of acute posterior MI. Patients with inferior MI who have either ST segment depression in leads V1 to V3 or ST segment elevation in the posterior leads V8 and V9 generally have larger infarction zones, lower resultant ejection fractions, and higher cardiovascular morbidity and mortality than patients with isolated inferior MI.45 Cardiac magnetic resonance imaging suggests these “posterior” infarctions producing tall R waves in leads V1 and V2 are actually lateral left ventricular wall MIs.6 A consensus document suggests reclassifying posterior infarctions as inferobasal infarctions.58

Right ventricular infarctions rarely occur in isolation and are usually associated with inferior or inferoposterior MI, although only about one third of inferior infarctions have associated infarction of the right ventricle. At times, an anterior MI involves some (but less than half) of the right ventricular wall. It follows that occlusion in any of the major coronary arteries may lead to right ventricular infarction, although the right coronary is most commonly involved. Clinically, right ventricular infarction features include elevated jugular venous pressure and hypotension in the setting of inferior wall MI. These findings, however, are also suggestive of pericardial tamponade. Nitrate-induced hypotension is also suggestive of right ventricular infarction, and of tamponade. Initial therapy for both would include volume loading and avoidance of vasodilators or other agents that may lower the blood pressure.

ST segment elevation in lead V1 in the setting of inferior MI (i.e., ST segment elevation in leads II, III, and aVF rather than in the setting of concomitant ST segment elevation in all anterior precordial leads) is suggestive of right ventricular infarction; this is not surprising in that lead V1 is the most rightward of the precordial leads. These changes occasionally extend into lead V2 with right ventricular infarction. ST
Segment elevation is usually greater in lead III than in lead II when right ventricular infarction coexists with inferior AMI. This logically follows in that (in the frontal plane) the positive vector of lead III is more rightward than that of lead II. Application of "right-sided" precordial leads is the best means to diagnose right ventricular infarction with the ECG. These leads, as a mirror image of the left precordial leads, demonstrate ST segment elevation with right ventricular infarction in leads V3R to V6R, with V4R having the highest sensitivity. ECG changes in the right-sided precordial leads with right ventricular infarction may be subtle owing to the smaller muscle mass of the right ventricle and the resulting diminution in QRS size (Fig. 76-9). Patients with inferior MI with concomitant right ventricular infarction have larger infarcts and experience more in-hospital complications and higher mortality rates.

Left main coronary artery occlusion. In a patient with symptoms of ACS, ST segment elevation in lead aVR should prompt consideration of occlusion of the left main coronary artery. Pooled data from several studies demonstrate that ST segment elevation in lead aVR (≥0.5 mV) is approximately 78% sensitive and 83% specific for left main disease; alternatively, this finding in lead aVR may represent multivessel disease, acute proximal left anterior descending occlusion, or (less commonly) left circumflex or right coronary occlusion. If ST segment elevation occurs both in leads aVR and V1, greater elevation in the former lead favors left main disease, whereas if it is greater in the latter lead, occlusion in the left anterior descending artery is more likely.

Electrocardiographic Differential Diagnosis of ST Segment Elevation

ST segment elevation on the ECG in the context of a presentation compatible with ACS is considered to represent acute myocardial ischemia until proved otherwise. Several other conditions, particularly left bundle branch block (LBBB) and LVH, also feature ST segment elevation that mimics infarction (see Table 76-4). Caution is required when interpreting ST segment elevation as to the decision to administer systemic fibrinolytic therapy.

Benign early repolarization is a normal electrocardiographic variant that does not imply, or exclude, CAD. BER includes the following electrocardiographic characteristics: (1) ST segment elevation; (2) upward concavity of the initial portion of the ST segment; (3) notching of the terminal portion of the QRS complex at the J point (i.e., junction of the QRS complex with the ST segment); (4) symmetrical, concordant T waves of large amplitude; (5) diffuse ST segment elevation on the ECG; and (6) relative temporal stability over the short term, although these changes may regress with old age. J point elevation is usually less than 3.5 mm, and the concave ST segment is usually elevated less than 2 mm (although it may be elevated as much as 5 mm in some cases) in the precordial leads and 0.5 mm in the limb leads. Maximal ST segment elevation in BER is typically seen in leads V2 to V5. Isolated BER in the limb leads is quite rare and should prompt reconsideration of AMI (Figs. 76-10A and 76-11). Reportedly 31% of predominantly white individuals less than 60 years of age who are resuscitated after idiopathic ventricular fibrillation have early repolarization changes in the inferolateral leads, as opposed to only 5% in a well-matched cohort of patients without syncope or heart disease. While significant malignant dysrhythmias may occur in patients with this electrocardiographic finding, there are many who do well over a lifetime.

Pericarditis, in the acute phase, features diffuse ST segment elevation as well. In pericarditis, the ST segments are concave.

**Figure 76-8.** Isolated posterior wall acute myocardial infarction (PMI); complexes from right precordial leads and posterior leads. The right precordial leads V1 and V2 reveal typical findings of PMI with prominent R wave (A), STD (B), and upright T wave (C). The posterior leads V8 and V9 in the same case demonstrate STE (arrows), confirming isolated PMI. STD, ST segment depression; STE, ST segment elevation.

**Figure 76-9.** Right ventricular infarction demonstrated with right-sided precordial leads (RV1 to RV6). This tracing is taken from the same patient as in Figure 76-7. The ST segment elevation of inferior acute myocardial infarction is still present, as is the reciprocal ST segment depression in leads I and aVL. The precordial leads are right-sided chest leads, as might be inferred from the relatively low voltage. ST segment elevation is noted in leads V3R to V6R, consistent with right ventricular infarction.
with an initial upsloping contour and are usually less than 5 mm in height. Occasionally, the initial contour is obliquely flat, but convex or domed ST segment morphology is suggestive of AMI. The ST segment elevation is usually seen in all leads with the exception of aVR (where it is depressed); V1 is variable. Focal pericardial inflammation is manifest as a more accentuated change in the leads reflecting the affected region. PR segment depression is an insensitive yet specific associated electrocardiographic finding in pericarditis, which is typically best seen in the inferior leads and in lead V6; correspondingly, PR segment elevation may be evident in lead aVR (Fig. 76-10; see Fig. 76-10B).

**Figure 76-10.** Noninfarctional ST segment elevation (STE). A, Benign early repolarization (BER) with concave STE. B, Acute pericarditis with concave STE and PR segment depression (upper two examples); concave STE without PR segment abnormalities (lower left example); and “reciprocal” STD and PR segment elevation in lead aVR (lower right example).

**Left ventricular aneurysm** (LVA), wherein a focal area of myocardium paradoxically bulges outward during systole, has characteristic electrocardiographic changes that can be difficult to differentiate from those of AMI. Considerable overlap exists between populations of patients with potential for AMI and LVA, and the electrocardiographic changes of LVA tend to be regional rather than diffuse.** Anatomically, LVA is most commonly found anteriorly, and changes are most often seen in leads V1 to V6 as well as leads I and aVL. ST segment elevation may be of any morphology (e.g., convex or concave), and Q waves may be present (Fig. 76-13). The calculation of the ratio of the amplitude of the T wave to the QRS complex may help distinguish acute anterior MI from LVA. If the ratio of the amplitude of the T wave to the QRS complex exceeds 0.36 in any single lead, the ECG probably reflects acute MI. If the ratio is less than 0.36 in all leads, however, the findings are probably due to ventricular aneurysm.

**Left bundle branch block** is a confounding pattern that reduces the ECG’s ability to detect ACS. A new, or presumably new, LBBB is strongly suggestive of ACS when noted in the appropriate clinical presentation. Preexisting LBBB, however, shares many ECG similarities to various electrocardiographic findings of ACS. In the right-sided precordial leads, ST segment elevation and tall, vaulted, upright T waves mimic those seen in acute anterior MI. The QS pattern of LBBB in these leads resembles the Q waves seen in infarction. Depressed ST segments with T wave inversions are seen in some or all of the lateral leads (V5, V6, I, and aVL) in LBBB; both of these resemble ischemic changes seen in ACS. Yet, these findings in LBBB are merely expressions of the “rule of appropriate discordance.” The ST segment and T wave vectors are expectedly discordant, or opposite in direction, to the major vector of the QRS complex in those leads. Since LBBB is a frequent finding on the ECG of a patient at risk for CAD, the normal findings in LBBB (Fig. 76-14) and the presentation of ST segment AMI in a patient with LBBB must be distinguished.

Sgarbossa used the Global Use of Streptokinase and t-PA for Occluded Coronary Arteries (GUSTO-I) trial database to obtain a population of patients with LBBB and enzymatic evidence of AMI. Three independent electrocardiographic

**Figure 76-11.** Benign early repolarization. Note the upwardly concave ST segment elevation, best seen in leads V4 to V6. The T waves are relatively large in the same leads. Subtle notching is also seen at the J point in leads V4 and V5. Prior electrocardiograms of this patient were unchanged.
Figure 76-12. Pericarditis. This tracing demonstrates several classic signs of pericarditis: (1) sinus tachycardia; (2) diffuse, concave upward ST segment elevation; (3) PR segment depression, best seen in lead II; and (4) PR segment elevation in lead aVR.

Figure 76-13. Left ventricular aneurysm: representative example of 12-lead electrocardiogram from patient with anterior left ventricular aneurysm. Note well-developed, completed Q waves in leads V2 through V5 and absence of reciprocal changes in contralateral leads. (Modified from Aufderheide TP, Brady WJ: Electrocardiography in the patient with myocardial ischemia or infarction. In Gibler WB, Aufderheide TP [eds]: Emergency Cardiac Care. St. Louis, Mosby, 1994, pp 169–216.)

Figure 76-14. Left bundle branch block (LBBB) (normal). This tracing demonstrates the classic findings of LBBB: (1) QRS complex width greater than 0.12 second; (2) absence of Q wave in lead V6; (3) broad monophasic R wave in leads V5, V6, I, and aVL; (4) discordant ST segment–T wave changes in leads V1 to V3 (simulating acute myocardial infarction), I, and aVL. A first-degree atrioventricular block is also apparent.

Predictors of MI in the presence of LBBB were identified: (1) ST segment elevation of at least 1 mm that is concordant with the QRS complex; (2) ST segment depression of at least 1 mm in lead V1, V2, or V3; and (3) ST segment elevation of at least 5 mm that is discordant with the QRS complex. These findings were assigned weighted scores of 5, 3, and 2, respectively. For accuracy in diagnosis, a specificity of 90% requires a score of at least 3. Thus, if an ECG features only discordant ST segment elevation of 5 mm or more but neither of the other two criteria, further testing is recommended before concluding that the ECG is indicative of AMI (Fig. 76-15). Subsequent literature yields mixed reviews of the Sgarbossa criteria for diagnosis of AMI in the presence of LBBB. Ultimately, the approach to the patient with LBBB and possible MI remains
Figure 76-15. Acute myocardial infarction (AMI) in left bundle branch block (LBBB). A, Using the Sgarbossa criteria, there is strong evidence of AMI because of the concordant ST segment elevation greater than 1 mm in leads II, V5, and V6; also suggestive is the ST segment depression seen in V2.

B, Again, applying the Sgarbossa criteria to this tracing with underlying LBBB, AMI is strongly suggested. There is concordant ST segment elevation in leads V5 and V6 that appears to exceed 1 mm; further, there is excessively discordant ST segment elevation in leads V2 and V3, probably greater than 5 mm.

complicated; diagnostic adjuncts to the history and physical examination (e.g., serial ECGs, comparison with prior ECGs, echocardiography, serum cardiac marker measurement) should be liberally employed when the ECG does not show obvious evidence of AMI as noted by the Sgarbossa criteria. A new LBBB together with a clinical impression of AMI remains an indication for fibrinolytic therapy or PCI.

Ventricular paced rhythms (VPRs) can mimic and mask the manifestations of AMI. VPRs originating in the right ventricular apex create a wide QRS complex, with a pseudo-LBBB pattern. As with LBBB, the right precordial leads in VPR typically feature predominantly negative QRS complexes with discordant ST segments and T waves that are elevated and tall or vaulted, respectively. Unlike LBBB, however, VPR originating in the right ventricular apex often yields a predominantly negative QRS complex in leads V5 and V6 as well (which is oriented leftward and slightly downward, whereas the impulse generated from the pacemaker wire is oriented superiorly). Furthermore, small vertical pacemaker spikes immediately preceding the QRS complex should be a clue to VPR, although these deflections are at times hard to detect on the 12-lead ECG.
Limited data exist to guide the clinician in interpretation of the 12-lead ECG in this setting. As with the LBBB scenario, the VPR pattern represents a significant confounding variable in the evaluation of the patient with chest pain suspected of having ACS. Sgarbossa and associates advanced criteria for detection of AMI in the presence of VPR that are similar to those for LBBB. These, too, are derived from the GUSTO-I database, but from a smaller group of patients. The criteria are essentially the same as the LBBB criteria: (1) ST segment elevation of at least 5 mm that is discordant with the QRS complex; (2) ST segment elevation of at least 1 mm that is concordant with the QRS complex; and (3) ST segment depression of at least 1 mm in lead V1, V2, or V3 (Fig. 76-16).

Left ventricular hypertrophy may mimic or obscure ACS on the ECG. LVH may feature prominent left-sided forces, manifesting as large rS or QS complexes in the right precordial leads—yet these changes seldom extend beyond V1 and V2 in the case of LVH. Consistent with the rule of appropriate discordance, the leads demonstrating such a pattern feature discordant ST segment elevation and tall, vaulted T waves, paralleling the changes of AMI. The initial portion of the elevated ST segment in LVH is generally concave, as opposed to the obliquely straight or convex pattern that usually (but not always) is seen with ST segment elevation in AMI. In LVH, the left precordial leads (and at times leads I and aVL) may show evidence of repolarization abnormality (or strain pattern), with ST segment depression and asymmetrically inverted T waves. The presence of this strain pattern in the left precordial leads is reassuring when attributing ST segment elevation and tall T waves in the right precordial leads to LVH rather
Non-ST Segment Elevation Acute Myocardial Infarction

This terminology supplants “non-Q wave MI,” previously termed “subendocardial infarction.” Precise terminology is difficult because Q waves may disappear with time and the criteria for “significant” Q waves vary. Moreover, transient ST segment elevation may simply be missed on ECG. Nonetheless, it is useful to describe the entity wherein there is serum marker evidence of MI in the appropriate clinical scenario but no captured ST segment elevation.

Pathophysiologically, total occlusion of the diseased artery may not have occurred, or the infarct zone may have been partially spared by collateral circulation or therapeutic intervention. ECG manifestations of non-ST segment AMI (NSTEMI) include ST segment depression and T wave inversion, which may be deep and symmetrical. Absence of STEMI, however, does not necessarily translate to better outcomes. A study analyzing over 250,000 AMI patients from the NRMI 2, 3, and 4 databases determined that patients with ST segment depression on the initial ECG have an in-hospital mortality rate of 15.8%—similar to that of patients with ST segment elevation or LBBB (15.5%). ST segment depression may herald true posterior infarction on the 12-lead ECG. Acute posterior (inferobasal) MI is one entity wherein emergent fibrinolysis or PCI is indicated in the absence of ST segment elevation on the 12-lead ECG.

Electrocardiographic Adjuncts in the Diagnosis of Acute Coronary Syndrome

Additional lead ECGs can increase sensitivity for AMI by evaluating regions of the heart prone to electrical silence on the 12-lead tracing. Most commonly, additional lead ECGs use posterior (leads V8 and V9) and right ventricular (RV4) electrodes, thus constituting the 15-lead ECG (Fig. 76-18). Posterior leads V8 and V9 are placed under the tip of the left scapula and at the left paraspinal area, at the same level as leads V4 to V6. Morphologic changes in the posterior leads may be subtle, principally because of the increased distance between these electrodes and the posterior wall of the heart (Fig. 76-19).

Electrocardiographic imaging of the right ventricle is enhanced with the use of the right-sided chest leads V1R to V6R (also termed RV1 to RV6). These are placed in mirror image fashion across the right precordium. Of the right precordial leads, V4R has the highest sensitivity for right ventricular infarction and is the lead of choice to include in the 15-lead tracing. Morphologically, less pronounced changes can be expected in the right-sided chest leads because of the relatively thinner wall of the right ventricle.

Use of the 15-lead ECG may improve diagnostic precision but does not appear to affect the rate of AMI diagnosis, use of reperfusion therapy, disposition, or outcome in patients with chest pain evaluated for ACS. In the subset of ED patients identified as candidates for admission to the cardiac care unit (i.e., high-risk patients), the 15-lead ECG increased the sensitivity of ACS detection by 12%. Possible applications for additional lead ECGs include the following: (1) ST segment changes (depression or elevation) in leads V1 to V3, either in an isolated lead or in more than one; (2) equivocal ST segment elevation in the inferior (II, III, aVF) or lateral (I, aVL) limb leads, or both; (3) all inferior STEMI; and (4) hypotension in the setting of ACS.

Serial ECGs and ST segment trend monitoring overcome the limitations of the snapshot 12-lead ECG. The use of increased electrocardiographic surveillance demonstrates diagnostic benefit in patients with recurrent or continuous chest
Figure 76-18. Fifteen-lead electrocardiogram (ECG) with inferior, lateral, posterior, and right ventricular acute myocardial infarction (AMI). The standard 12-lead ECG reveals the typical ST segment elevation (STE) in the inferior and lateral leads as well as ST segment depression (STD) with prominent R wave in the right precordial leads. Posterior AMI is indicated by both the right precordial STD with prominent R wave and the STE in posterior leads V8 and V9. Note that the degree of STE is less pronounced than that seen in the inferior leads because of a relatively longer distance from the posterior epicardium to surface leads. The right ventricular infarction is noted in this case using the simplified approach with only RV4, which demonstrates STE of relatively small magnitude.

Figure 76-19. Schematic of thorax depicting single anterior and posterior complexes in posterior wall acute myocardial infarction (AMI). The standard electrocardiographic precordial (anterior) leads image the posterior wall of the left ventricle from the anterior perspective of the thorax. Acute infarction of this region manifests electrocardiographic changes that are frequently the reverse of the typical abnormalities of AMI. In this schematic example, lead V1 reveals ST segment depression with an upright T wave and prominent R wave. Use of the posterior lead V9 demonstrates ST segment elevation, consistent with AMI.

Figure 76-20. Eleven-lead electrocardiogram (ECG) showing patterns of ST segment elevation and depression in anterior and posterior infarctions. The standard 12-lead ECG reveals the typical ST segment elevation (STE) in anterior leads as well as ST segment depression (STD) with prominent R wave in the right precordial leads. Posterior AMI is indicated by both the right precordial STD with prominent R wave and the STE in posterior leads V8 and V9. Note that the degree of STE is less pronounced than that seen in the inferior leads because of a relatively longer distance from the posterior epicardium to surface leads. The right ventricular infarction is noted in this case using the simplified approach with only RV4, which demonstrates STE of relatively small magnitude.

Measuring QT dispersion may facilitate risk stratification, assessment of therapeutic success, and monitoring of ongoing pharmacotherapy. QT dispersion is the calculated difference between the longest and shortest QT intervals on a 12-lead ECG. Ischemic myocardium has a prolonged repolarization time, and the QT interval measures time from ventricular depolarization to repolarization. Increased variability in measured QT intervals translates to greater QT dispersion, which reflects underlying regional ischemia. Comparing ACS or AMI patients with those found to be free of such disease reveals a difference between populations in QT dispersion values. 

Body surface mapping increases the amount of electrocardiographic data for processing and decision-making. Whereas serial ECGs and ST segment trend monitoring increase the period of time over which data are collected on a 12-lead ECG, body surface mapping increases the number of electrodes used to gather data and increases the vantage points from which the heart is evaluated. Various devices use between 40 and 120 leads. With an 80-electrode device, 64 chest and 16 back electrodes are applied in a vest-like fashion with self-adhering strips. Recording from all electrodes simultaneously, the body surface map enters ST segment elevation and depression data into a computer, which transforms the data into a color-coded torso image. With red representing ST segment elevation, blue signifying ST segment depression, and green reflecting normal, degree of disease is also expressed in terms of color intensity. 

Body surface mapping may increase sensitivity for MI, especially in areas that are relatively electrically silent.

pain, particularly in patients with an initially normal nondiagnostic or possible ST segment mimicking syndrome (i.e., ST segment elevation potentially resulting from BER) ECG. Examining ST segment trends (measured every 20 seconds for at least the first hour) and automated serial ECGs (at least every 20 minutes) in ED patients with chest pain can significantly increase the sensitivity and specificity for detection of AMI (16%) and ACS compared with that of the initial ECG. In more than 600 patients admitted with nondiagnostic initial ECGs and symptoms consistent with ACS, 12 hours of continuous 12-lead ECG monitoring in a coronary care unit setting revealed that only serum cardiac marker elevation and presence of ST segment episodes (defined as ST segment elevation or depression more than 1 mm different from baseline that endured for at least 1 minute) predict cardiac death or MI.
Figure 76-20. Serial electrocardiography. A, Representative example of lead III in a patient with chest pain and an initially nondiagnostic electrocardiogram depicting the evolution of ST segment elevation acute myocardial infarction (STE AMI). B, Representative example of lead V2 in a patient with the left ventricular hypertrophy pattern. Serial sampling of this patient with ongoing chest pain and a confounding electrocardiographic pattern reveals the progression to STE AMI. C, Representative example of lead V3 in a patient with left bundle branch block and evolving AMI. D, Representative examples of lead III in a patient with chest pain and noninfarctional STE; note the lack of change (degree of elevation as well as morphology of elevation) over time in this patient with benign early repolarization.

on the 12-lead ECG (e.g., posterior and lateral walls of the left ventricle and the right ventricle) and in patients with underlying LBBB.75–77

Limitations of Electrocardiography in Acute Coronary Syndrome

The sensitivity and specificity of a single ECG for AMI are approximately 60% and 90%, respectively. Serial ECGs in the setting of continued or recurrent pain increase the diagnostic utility.78 The initial ECG is nondiagnostic in approximately half of the patients presenting to the ED who are ultimately diagnosed with AMI. Moreover, nondiagnostic and even normal ECGs do not exclude the diagnosis for AMI since around 20% of patients ultimately diagnosed with AMI have nondiagnostic ECGs earlier in their course. As time elapses from symptom onset to ECG recording, the ability of the ECG to exclude AMI does not markedly increase.39 Thus, a single normal or nondiagnostic ECG does not ensure absence of ACS, even if the ECG was recorded well after the onset of symptoms. In patients being evaluated for ACS, only serial electrocardiography, combined with serial cardiac marker determinations, can exclude AMI, and even then UA without actual myocardial necrosis may be present.

Chest Radiography

The chest radiograph provides information concerning the application of therapies (i.e., an evaluation of mediastinal width in the consideration of fibrinolytic agent use and the determination of pulmonary congestion in the consideration of acute parenteral beta-adrenergic blocking therapy). Further, the presence of CHF on the chest radiograph increases risk in AMI patients who may benefit from an aggressive therapeutic approach.

There is radiographic evidence of pulmonary congestion in approximately one third of AMI patients. AMI patients who develop CHF have increased mortality, as reported by the Killip classification. The chronicity of the CHF syndrome may also be suggested by the heart size. Patients who present with AMI complicated by pulmonary edema and have a normal heart size most often have no past history of CHF. In fact, AMI is the most frequent cause of pulmonary edema with a normal cardiac size. In other instances, patients with AMI and cardiomegaly with or without pulmonary edema frequently have a preexisting history of CHF, anterior wall infarct, and multiple-vessel CAD (Fig. 76-21).

Serum Markers

Biochemical markers play a pivotal role in the diagnosis, risk stratification, and guidance of treatment. The European Society of Cardiology and ACC define the criteria for AMI diagnosis on biochemical grounds since specific markers, particularly the troponins, indicate irreversible cell damage.11 In the past, detection of AMI by characteristic enzyme elevations over 48 to 72 hours was sufficient to establish the diagnosis of AMI because there was essentially no specific therapy to reverse or prevent the developing myocardial necrosis. The evolution of fibrinolytic therapy and acute intervention create significant pressure to identify patients with AMI.

For patients with a nondiagnostic ECG, early elevation of serum markers of myocardial necrosis confirms a presumptive diagnosis of NSTEMI. Caution is advised, however, when a single serum marker is not elevated. This single test is too insensitive to be used to support a decision that the patient can be discharged, or that no acute coronary event has occurred. The patient’s history remains the most vital portion of the diagnostic evaluation of potential ACS. Serial testing substan-

Figure 76-22. Serum marker sensitivity relative to the time of onset of chest pain in the patient with acute myocardial infarction. Data obtained from the medical literature. AMI, acute myocardial infarction; CK-MB, creatine phosphokinase MB fraction.

Tially improves the sensitivity of these tests (Table 76-6 and Fig. 76-22).79

Troponins

Because of their superior sensitivity and specificity compared with CK-MB, cardiac troponins are the best markers for myocardial cell injury. Two myocardium-specific proteins, myocardial troponin I (TnI) and troponin T (TnT), precede the release of CK-MB into the serum. The cardiac troponins are genetically distinct from troponin forms found in other muscle tissue, rendering them highly cardiac specific. Monoclonal antibodies have little cross-reactivity with troponins from skeletal muscle. Troponins I and T are very similar in their diagnostic and prognostic utility as well as their serum kinetics and rates of rise and fall associated with myocardial ischemia, infarction, and ACS.

The biokinetics of troponin release relate to the location of the protein within the cell. Normally, small quantities of troponins are free in the cytosol, and the majority is entwined in the muscle fiber. After injury, a biphasic rise in serum troponins corresponds to early release of the free cytoplasmic proteins, followed by a slower and greatly prolonged rise with breakdown of the actual muscle fiber. The slow destruction of the myocardial cell contractile proteins provides a sustained release of the troponins for 5 to 7 days. Serum troponin concentrations begin to rise measurably in the serum at about the same time as CK-MB elevations become detectable, as early
as 3 hours after onset, but troponin levels remain elevated for 7 days or more.

The cardiac-specific troponins, determined serially, are highly sensitive for the early detection of myocardial injury. A positive test result is associated with significant risk, and serial negative results predict low risk. A single troponin measurement on presentation, however, has limited utility in excluding AMI and no ability to detect UA without infarction because cell injury is required and because of the time delay in the rise in levels (which may not be detected until 10 hours after symptom onset in some AMI patients). Serial measurements, particularly when performed at least 6 hours after symptom onset, markedly improve the sensitivity of the cardiac troponins for AMI, and the pattern of rise may assist in determining the acuity of the event. The sensitivity of TnT approaches 50% within 3 to 4 hours of the event. The test result is positive in about 75% of patients at 6 hours after onset of symptoms; at 12 hours, the test is almost 100% sensitive. A single troponin determination, however, may have utility in evaluating patients who present several days into a syndrome of atypical chest pain that is felt possibly, but unlikely, to represent an ACS event. Further, a single serum troponin value may also have utility in elderly patients with nonspecific presentations for ACS, particularly with respect to TnI. Physicians therefore must be familiar with the sensitivity and limitations of the particular assay used at their institution and the cutoff concentrations for clinical decisions.

Multiple studies have indicated that even very low levels of troponin elevations are associated with significant adverse clinical prognosis. In a number of studies, up to 33% of patients diagnosed with UA with normal CK-MB levels had elevated troponin levels, indicating the markers' improved sensitivity for myocardial cell injury. The fact that the risk of these patients for cardiac events and mortality is similar to that of the patients diagnosed with AMI by traditional WHO criteria led to the redefinition of AMI on the basis of biochemical markers. On the basis of data from the Thrombolysis in Myocardial Infarction-IIIB study, there is almost a linear correlation between increasing troponin levels and risk of cardiac events and mortality, even in patients with a nondiagnostic ECG and normal CK-MB levels. In a review of over 7000 NSTEMI patients, troponin levels identified patients at low mortality risk. Small elevations of troponin may be used as an objective measure of "preinfarcts" that characterize UA and are associated with increased risk of infarction in the near term. Marked elevations in troponin consistent with AMI represent further progression along the continuum of ACS toward "traditional" AMI.

Cardiac troponins may also guide ACS treatment. Data from the Treat Angina with Aggrastat and Determine Cost of Therapy with an Invasive or Conservative Strategy-Thrombolysis in Myocardial Infarction (TACTICS-TIMI 18) trial suggest that patients with elevated troponin who are treated with an early invasive interventional strategy within 48 hours have a marked improvement in recurrent ischemia, infarction, and mortality both in the short term and at 6 months.

*Results from meta-analysis of several studies, with random effects calculations unless otherwise indicated.
†Point estimate from a single study or a range of reported values; meta-analysis not performed.
ACS, acute coronary syndrome; AMI, acute myocardial infarction; CI, confidence interval; CK-MB, creatine phosphokinase MB fraction; ECG, electrocardiogram.
These studies included patients without major ECG criteria for immediate interventional reperfusion strategies. The use of glycoprotein IIIb/IIIa inhibitors (GPIs) in patients with elevated troponins may prevent early complications in patients with ACS. It is likely that the improved sensitivity of troponin has captured a high-risk ACS population not previously diagnosed or treated. Importantly, elevated troponin levels identify those patients with UA or NSTEMI who stand to gain the greatest benefit from an early invasive strategy with coronary angiography and revascularization.

Elevated troponin levels occur in a variety of cardiac and noncardiac conditions unrelated to the typical ACS and AMI pathophysiology. Cardiac conditions that can result in significant increased troponin levels in patients without evidence for ACS include myocarditis, pericarditis, CHF, LVH, and non-penetrating cardiac trauma. While the presence of elevated troponin levels in these conditions might be considered false-positive results, data support the contention that the source of these levels is underlying noninfarction myocyte injury that occurs with these conditions. Moreover, elevated troponin levels in these non-ACS cardiac conditions have prognostic significance.

Troponin elevations can also be seen in noncardiac conditions including pulmonary embolism (PE), sepsis, and renal insufficiency. Troponin elevation may result from right ventricular dysfunction and myocyte injury in the case of submassive and massive PE, and is a significant predictor of adverse outcome. Similar elevated troponin levels are reported in patients with sepsis and critically ill patients with multiple organ system failure.

Elevated troponin levels are commonly seen in asymptomatic patients with end-stage renal disease. This finding may relate to the high prevalence of cardiac disease in this population rather than any reduced renal clearance, and may still represent evidence of subclinical myocardial damage. The TnT isoform is associated with elevated levels in renal failure more than TnI, particularly in patients on hemodialysis. Elevated troponin levels in the setting of renal failure are associated with increased risk of death and major cardiac and vascular morbidity and should not be ascribed to chronic renal failure unless old records are present to corroborate that the elevated troponin level is actually the patient’s normal baseline level.

Creatinine Phosphokinase
Creatinine phosphokinase (CK) is found in large quantities not only in cardiac muscle but also in skeletal muscle, brain, kidney, lung, and the gastrointestinal tract. Myocardial cells are by far the most abundant potential sources of CK-MB; thus, the appearance of CK-MB in the serum is highly suggestive of MI. The CK-MB fraction remains the best alternative to the troponins as a cardiac marker. In the setting of AMI, CK-MB is released and is detectable in the serum as early as 3 hours after onset of the necrosis. CK-MB characteristically peaks at 20 to 24 hours and becomes normal within 2 to 3 days after injury. Elevated CK-MB values identify a patient at considerable risk for a poor outcome but do not correlate well with infarct size. Unfortunately, skeletal muscle does contain small amounts of CK-MB, particularly the pelvic musculature. Abnormal CK-MB elevations may be seen in trauma, muscular dystrophies, myositis, rhabdomyolysis, and after extremely vigorous exercise.

The sensitivity of a single CK-MB determination in diagnosing AMI is dependent on the elapsed time from chest pain onset. Values obtained within 3 hours of onset are poor diagnostic tools, with a sensitivity of only 25 to 50%. CK-MB determinations obtained beyond this 3-hour time period have increasing sensitivities for the diagnosis of AMI, ranging from 40% to nearly 100%, particularly when obtained 12 to 16 hours after onset. As a result, the use of single determinations of CK-MB is of little value in excluding ACS. Serial sampling, even over relatively short time periods (12 hours), increases sensitivity considerably, particularly when considered with serial electrocardiography and repeated assessments of the patient. Diagnostic utility is also improved by requiring that the CK-MB value not only be elevated but also be at least 5% of the total CK value. False-positive elevations can occur with noncoronary conditions such as pericarditis, myocarditis, skeletal muscle disease, rhabdomyolysis, trauma, and exercise.

Myoglobin
Myoglobin, a small protein (17,000 daltons) found in muscle tissue, is rapidly released into the circulation after cellular injury. In cases of myocardial injury, myoglobin rises in the initial 1 to 2 hours, peaks at 5 to 7 hours, and returns to baseline by 24 hours. Because of its rapid rise, myoglobin is attractive as an early indicator of myocardial injury. Myocardial myoglobin, however, is not currently distinguishable immunologically from skeletal muscle myoglobin. Thus, myoglobin is elevated in any clinical situation involving the skeletal muscle, such as trauma, exercise, and significant systemic illness. In addition, myoglobin increases are seen in patients with renal failure because of reduced clearance.

The sensitivity of an initial myoglobin at presentation for AMI varies from as low as 21% to as high as 100%. Serial testing at 2 to 4 hours after presentation significantly improves the assay’s diagnostic power. A doubling of the level as soon as 1 to 2 hours after the initial measurement greatly increases the sensitivity for the diagnosis of AMI, but this approach is very nonspecific. The value of myoglobin may be in its excellent negative predictive power for AMI and its early rise kinetics compared with other markers. Although some evidence suggests that a normal myoglobin value 2 hours after presentation may be used safely to rule out active AMI but not ACS, myoglobin has largely fallen out of favor.

Other Cardiac Markers
Troponin, CK, and myoglobin are all measures of myonecrosis. Biochemical assays for potential new cardiac markers for necrosis are being developed in the hope of finding ones with improved sensitivity, risk determination capability, and prognostic power. One such new cardiac-specific myonecrosis marker is heart-type fatty acid–binding protein. Other potential markers for utility in ACS include those that may detect ischemia prior to actual necrosis, and plaque instability or inflammation.

Episodes of ischemia can result in biochemical changes prior to actual irreversible cell necrosis. Ischemic-modified albumin (so-called cardiac albumin) is a potentially useful ACS biomarker that reportedly detects early myocardial ischemia rather than the later myocyte necrosis, and may have even earlier elevation than myoglobin. Other potential ischemia markers include unbound free fatty acids and whole blood choline levels. Markers of hemodynamic status, including the natriuretic peptides, may also have utility in ACS. These markers such as B-type natriuretic peptide (BNP) and NT-proBNP are released from cardiac myocytes in response to increases in ventricular wall stress. BNP is most commonly used as a marker for CHF, but is a useful adjunct to the standard cardiac markers, and has good predictive power for recurrent ACS events and cardiac-related deaths, as well
as CHF exacerbations, in patients with AMI. Moreover, the natriuretic peptides are excellent predictors of both short- and long-term mortality in patients with UA, NSTEMI, and STEMI.

Given the underlying pathophysiology of ACS, a variety of biochemical markers for inflammation and plaque instability may prove useful in evaluating risk of a cardiac event. Chief among these is the inflammatory marker C-reactive protein (CRP) and high-sensitivity CRP (hsCRP), which have long-term prognostic value for cardiac events in healthy individuals as well as potential short-term prognostic value when combined with other markers for ACS. Other inflammatory markers include interleukin-6 and tumor necrosis factor alpha. Elevated plasma levels of myeloperoxidase, an abundant leukocyte enzyme found in vulnerable coronary plaques that have ruptured, predict short-term risk of adverse cardiac events even with negative cardiac troponin and no evidence of myocardial necrosis.

Multiple Marker Strategies

Diagnostic, risk stratification, and prognostic accuracy might be enhanced by the utilization of multiple markers for AMI and ACS. The combination of CK-MB and myoglobin measurement has a sensitivity from 62 to 100% and specificity from 72 to 89% for AMI on presentation. Serial measurements of these markers significantly improve the performance of this combined marker approach. McCord reported on the utility of a multimarker strategy using the early but noncardiac-specific marker myoglobin with the more specific and prognostic marker TnI. In 817 patients evaluated for ACS in the ED, the combined marker approach had a sensitivity of 96.9% and negative predictive value of 99.6% for AMI when applied at presentation and at 90 minutes. Similarly, the utility of a three-marker approach (CK-MB, TnI, and myoglobin) in an accelerated critical pathway reported 100% sensitivity and 100% negative predictive power for AMI in 1285 patients assessed for ACS.

In a large series of ED chest pain patients with an initial nondiagnostic ECG, a 2-hour delta CK-MB combined with a 2-hour delta troponin I had a sensitivity of 93% and specificity of 94% for AMI. Other multimarker strategies include combining measurement of a conventional marker for myocardial necrosis (troponin) with a marker for inflammation (CRP) and a hemodynamic marker (BNP). Many of these multimarker strategies, however, have low specificity. As a result, a positive multimarker test requires confirmation with later-appearing, more definitive cardiac biomarkers. Thus, the multimarker approach does not offer substantial benefit over the individual biomarker determinations and is therefore not recommended.

Echocardiography

Two-dimensional echocardiography detects regional wall motion abnormality associated with ACS. Impaired myocardial contractility can range from hypokinesis to akinesis. Impaired myocardial relaxation during diastole results in decreased ventricular distensibility. After AMI, paradoxal wall motion and decreased ejection fraction observed during systole indicates the subsequent loss of muscle tone from necrosis.

Particularly in individuals with nondiagnostic ECGs, the presence of regional systolic wall motion abnormalities in a patient without known CAD is a moderately accurate indicator of acute myocardial ischemia or infarction, with a positive predictive accuracy of about 50%. The age of wall motion abnormalities, however, often cannot be determined without prior echocardiograms.

The absence of segmental abnormalities (presence of either normal wall motion or diffuse abnormalities) has a significant high negative predictive value, as high as 98% for cases of suspected MI. Moreover, segmental wall motion abnormalities can be seen not only in the zone of acute infarction but also in regions of ischemic stunning. Resting echocardiography provides an assessment of global and regional function, an important predictor of complications and mortality in patients with ACS. Data from the ACC/AHA task force indicate that patients with mild and localized as opposed to extensive wall motion abnormalities have a low risk of ACS complications.

In addition, echocardiography can help evaluate other causes of clinical presentations mimicking ACS, including valvular heart disease, aortic dissection, pericarditis, mitral valve prolapse, and pulmonary embolus. Finally, echocardiography is an important tool to assess for various complications of AMI, including acute mitral regurgitation, pericardial effusion, ventricular septal and free wall rupture, and intracardiac thrombus formation.

Technical limitations restrict the use of echocardiography in the ED. These limitations include the quality of the study and the expertise of the reader interpreting the study at the patient’s bedside. Injury involving more than 20% of the myocardial wall is required before segmental wall motion abnormalities can be detected echocardiographically. In addition, the inability of the two-dimensional echocardiogram to distinguish between ischemia, AMI, or old infarction and the potential absence of wall motion abnormality in nontransmural infarctions can further limit the usefulness of two-dimensional echocardiography.

Stress echocardiography, as opposed to resting echocardiography, can detect CAD as well as assess cardiac function early after an AMI. This can be performed with graded increases in cardiac workload, either by standardized exercise or pharmacologic adrenergic stimulating agents such as dobutamine. In addition, vasodilating agents, such as dipyridamole and adenosine, induce heterogeneous myocardial perfusion and reveal functional myocardial ischemia in susceptible patients. Stress echocardiography is superior to conventional treadmill testing for CAD in women. Graded dobutamine stress echocardiography assesses myocardial viability and ventricular function within the first few days after an AMI. Clinical studies of patients with nondiagnostic ECGs, negative markers, and negative rest echocardiography suggest a role for emergency pharmacologic stress echocardiography as a provocative test after a period of observation with at least two marker and ECG assessments in a chest pain or ED observation unit.

Myocardial contrast echocardiography (MCE) uses microbubble ultrasonic contrast agents to assess microvascular perfusion and regional function with echocardiography. MCE evaluation of perfusion and regional function is able to accurately risk stratify ED patients with chest pain and nondiagnostic ECGs even before serum markers are available. Other smaller studies have reported low rates of adverse cardiac events in chest pain patients with normal MCE findings following a nondiagnostic ECG and negative serum markers. The clinical value of MCE in the ED, like resting and stress echocardiography, remains uncertain.

Myocardial Scintigraphy

Radionuclide tracer injection and scintigraphy, such as with single-photon emission computed tomography (SPECT), allows real-time assessment of myocardial perfusion and function. Technetium-99m sestamibi has a slow redistribution to ischemic myocardium. This property allows immediate injection and imaging, which detects altered distribution consistent
Computed Tomography

Computed tomography imaging is a noninvasive imaging modality to assess for ACS. Electron beam computed tomography (EBCT) was introduced nearly two decades ago to screen for coronary calcium as a marker of underlying atherosclerotic heart disease and risk of ACS. While calcium scoring systems exist to assess cardiovascular disease risk, there are few studies that have examined the role of EBCT in the assessment of patients with acute chest pain. The few studies that examine EBCT demonstrate good sensitivity and excellent negative predictive value for subsequent cardiac events, but have design limitations.

Technical advances in imaging include multidetector computed tomography (MDCT) with multislice 16-, 64-, and 256-slice CT scanning, as well as ECG-gated MDCT. These may revolutionize noninvasive cardiovascular imaging in the setting of ACS. These enhancements allow imaging of the beating heart with minimal motion artifact and accurate resolution to the level of the coronary vessels. Improvements in image reconstruction and reformating software allow not only direct visualization of the coronary arteries, or CT angiography (CTA), but also can provide functional information on perfusion, wall motion, and left ventricular ejection fraction.

The utility of MDCT in the ED focuses on two potential protocols, a coronary CTA by MDCT and a more global “triple rule-out” thoracic or chest MDCT. Noninvasive coronary CTA by MDCT performs well when compared with standard invasive coronary angiography. Cardiac CT provides excellent detection of calcified and noncalcified coronary artery plaque and stenosis, indicative of atherosclerosis and risk of ACS. CTA may be less useful, however, in a patient with some form of ischemic heart disease, followed by subsequent scanning, which provides more definitive data regarding the particular subtype of ACS. In patients with a normal initial study, the likelihood of ACS is extremely low. In patients with an initial study revealing abnormal distribution (i.e., reduced uptake) of the tracer, some form of ischemic heart disease is likely. Subsequent imaging then reveals one of two patterns: normal redistribution (normal uptake) or continued reduced uptake. The redistribution pattern is consistent with active coronary ischemia and the continued reduced uptake is found in patients with MI, either remote or recent. Myocardial scintigraphy has promising positive and negative predictive values for cardiac events with high sensitivity and a good specificity for CAD.

Immediate myocardial scintigraphy is useful in detecting ACS and risk of cardiac events in selected patients presenting at the ED with atypical chest pain, nondiagnostic ECGs, and low to moderate risk of AMI. Multiple studies find a relatively high incidence of cardiac events, presence of AMI, and need for revascularization in patients with a positive nuclear scan. The probability of a cardiac event is 10-fold higher in patients with abnormal scans than in patients with a normal scan. The incidence of cardiac events with a normal scan is lower than 1% for the 30-day period following the index study. Myocardial scintigraphy can reduce the number of patients admitted from the ED with chest pain who are ultimately determined not to have ACS without reducing appropriate admissions for patients with ACS.

Myocardial scintigraphy studies are difficult to perform early after the patient’s presentation to the ED. Radioisotopes and the personnel to administer them may not be immediately available and physician interpretation experience quite variable. Studies of ED perfusion imaging are resting studies, rather than more provocative stress (exercise or pharmacologically induced) perfusion studies.

Graded Exercise Testing

Exercise stress testing for ED patients is feasible. In over 1000 patients with low-risk chest pain (5% incidence of CAD) who underwent exercise testing after negative serial markers and 9 hours of ECG monitoring in the ED, stress testing had a negative predictive value of 98.7% for the diagnosis of ACS or cardiac event within 30 days. An abbreviated ED-based “rule out MI” protocol followed by mandatory stress testing appears to be an effective diagnostic method for the detection of symptomatic CAD in low- to moderate-risk patients.

ACC/AHA guidelines on exercise testing state that such testing can be performed when patients are free of active ischemic or heart failure symptoms for a minimum of 8 to 12 hours. Immediate stress testing without the rule-out evaluation, however, may be safe and cost effective in patients with chest pain felt possibly to be of cardiac origin, but with low suspicion of ACS. To determine the safety and utility of immediate exercise testing in the ED, 1000 low-risk patients underwent immediate exercise testing with no adverse effects. Six hundred forty patients (64%) had negative exercise test results, all of whom were discharged home from the ED. The rate of CAD diagnosis or cardiac event within 30 days was 29% for the positive stress group, 13% for the nondiagnostic group, and 0.3% for the negative stress group. In total, 30-day follow-up was achieved in 888 (89%) patients and revealed no mortality in any of the three groups.

Graded exercise testing in the ED at most institutions is not available continuously. The mortality rate is extremely low (1 in 2500), but absolute contraindications include recent AMI (within 2 days), high-risk UA, uncontrolled cardiac dysrhythm-
mias causing symptoms or hemodynamic compromise, symptomatic severe aortic stenosis, uncontrolled symptomatic heart failure, acute pulmonary embolus or infarction, acute myocarditis or pericarditis, and acute aortic dissection.123

Patients with a high pretest probability of CAD have a significant rate of false-negative results, and patients with a low pretest probability have a significant rate of false-positive stress test results. The specificity of the test is decreased in the presence of underlying electrocardiographic abnormalities secondary to medications, electrolyte abnormalities, LVH, or artifact. A false-positive test outcome may result from aortic stenosis or insufficiency, hypertrophic cardiomyopathy, hypertension, arteriovenous fistula, anemia, hemoglobinopathies, low cardiac output states, chronic obstructive pulmonary disease, digitalis toxic states, LVH, hyperventilation, mitral valve prolapse, and bundle branch blocks. An increase in the rate of false-positive test results in women tends to decrease the usefulness of graded exercise testing in this population.

ED-BASED CHEST PAIN CENTERS

These specialized units for the lower-risk population are utilized in 30% of the EDs in the United States. The goal of the chest pain center (CPC) is to provide an integrated approach to patients with chest pain or potential ACS that includes rapid triage, early identification, and treatment of high-risk ACS patients and risk stratification for low-risk patients. Guidelines and critical pathways play an essential role in the CPC process. Staff, resources, and space are often dedicated for a CPC, but the unit can be part of an ED observation unit or a “virtual” unit located near or within the ED.

A CPC protocol should rapidly direct patients with possible ACS into a high-level treatment area where an ECG and clinical examination can be obtained within the first 10 minutes. Patients with STEMI requiring immediate reperfusion therapy or with UA in need of further intervention can be identified quickly. This goal can be combined with an efficient ED evaluation of patients with low to moderate risk of ACS. The greatest medical benefit from the CPC is the early identification of patients with AMI and UA; the most significant financial impact is the reduction of inappropriate hospital admissions.

The National Heart Attack Alert Program (NHAAP) of the National Heart, Lung, and Blood Institute (NHLBI) challenges clinicians to provide care for ED patients with clear symptoms and signs of AMI within 30 minutes of arrival. The NHAAP recommends (1) a specific area of the ED equipped for assessing and monitoring patients potentially having ischemia, including standing orders for initial diagnostic and therapeutic actions; (2) a standing protocol with inclusion and exclusion criteria for reperfusion therapies, including language authorizing the physician to administer fibrinolytic therapy or to mobilize the catheterization laboratory for prespecified cases; (3) a clear demarcation of responsibilities for all members of the reperfusion team; and (4) policies and procedures for the treatment and possible transfer of patients with ST segment elevation AMI who are ineligible for fibrinolytic therapy.

These recommendations highlight the advantages of a target “door-to-drug” time of 30 minutes (or less) or a door-to-catheter (where percutaneous procedures are available) time of 90 minutes (or less) for patients with typical presentations of AMI with ST segment elevation. For example, the CPC can have assigned nursing personnel who rapidly evaluate the patient with chest pain with a 12-lead ECG, as well as screening vital signs and cardiac monitoring, and deliver the ECG directly to a clinician capable of making a decision about activation of the catheterization laboratory or administration of fibrinolytic therapy.

The CPC may also be used as an observation and evaluation unit where patients with chest pain and low to intermediate clinical likelihood of ACS can be monitored with electrocardiography, ST segment trending, serial 12-lead ECGs, and sequential serum markers. In addition, many CPCs now employ further ACS evaluation with stress testing, echocardiography, or myocardial scintigraphy before disposition.125 Significant cost savings occur, with typical charges and actual costs ranging from 20 to 50% of the costs for the usual inpatient approach.

The Chest Pain Evaluation in the Emergency Room (CHEER) investigators in a prospective, randomized trial compared a CPC with the traditional hospital admission to rule out MI.126 Over a 16-month period, patients with chest pain at intermediate ACS risk on the basis of history, examination, and ECG were randomly assigned to either CPC or hospital admission. CPC patients underwent serial serum marker and ECG determinations over a minimum of 6 hours. If investigations were negative and the course was uncomplicated, patients were elevated with an exercise stress test, nuclear stress test, or stress echocardiography. If the results of this evaluation were positive, the patient was admitted; if negative, the patient was discharged with cardiology follow-up within 72 hours. In the CPC group, all events occurred among those with a positive stress test result; no cardiac events occurred in the negative stress test group after ED discharge. Admissions were reduced by 45.8%.

A chest pain accelerated diagnostic protocol approach to low- to intermediate-risk patients can be feasible, safe, and effective.121 In a study of comprehensive diagnostic 9-hour evaluation (Heart ER Program) for 1010 patients with possible ACS, patients underwent serial testing with the following: CK-MB at presentation, 3, 6, and 9 hours; continuous 12-lead ECGs; and serial ST segment trend monitoring. Two-dimensional echocardiography and graded exercise testing were performed in the ED after the 9-hour evaluation.

Approximately 80% of patients with chest pain can be safely evaluated in the ED with ultimate discharge to home. The resources required for a successful CPC-based operation in which patients undergo rapid exclusion of ACS through serial testing, continuous monitoring, and immediate provocative stress testing are considerable. Although studies suggest that CPCs decrease the number of admissions, they may increase the number of patients seen in the ED for chest pain, and physicians may overuse the CPC accelerated diagnostic protocol approach in patients whom they would otherwise have discharged.127 Other issues to consider include cardiologist support and the impact on primary care physicians.

MANAGEMENT OF ACUTE CORONARY SYNDROME

The pathophysiology of an acute coronary event includes (1) endothelial damage through plaque disruption, irregular luminal lesions, and shear injury; (2) platelet aggregation; (3) thrombus formation causing partial or total lumen occlusion; (4) coronary artery vasospasm; and (5) reperfusion injury caused by oxygen free radicals, calcium, and neutrophils. In patients with noninfarction ACS, spontaneous fibrinolysis of the thrombus occurs rapidly, minimizing ischemic insult; persistence of the occlusive thrombus, however, results in MI.

Relationship of Time to Treatment with Outcome

The beneficial effect of reperfusion is a function of the length of ischemic time. In the late 1970s, the wave front phenomenon of ischemic cell death hypothesized that myocardial
necrosis progresses from the subendocardium to the epicardium after coronary occlusion (Fig. 76-23). Early patency resulting in myocardial salvage is the key benefit of emergent revascularization therapy using either fibrinolysis or primary angioplasty. Treatment within the first hours after symptom onset may result in substantial myocardial salvage. Delivered at a later time, from 2 to 12 hours after AMI onset, treatment may result in a modest yet significant benefit. The opening of the occluded artery causes less adverse ventricular modeling, reduces occurrence of ventricular aneurysm, increases blood flow to myocardium, and improves electrophysiologic stability. In the angiographic substudy of GUSTO, preserved left ventricular function and mortality at both the 24-hour and the 30-day end points related to angiographic patency at 90 minutes.128 Fibrinolytic therapy of patients with AMI had significantly greater benefit for those treated within the first 1 or 2 hours compared with those treated later. In the Myocardial Infarction Triage and Intervention (MITII) trial, the mortality rate among patients treated within 70 minutes was 1.3% compared with 8.7% in those treated later.129

Substantial delays often occur between symptom onset and hospital-based initiation of fibrinolytic therapy. In 1991, the NHLBI launched the NHAAP to promote the rapid identification and treatment of AMI. The factors responsible for delay in the care of AMI patients are grouped by the NHAAP into three phases: patient-bystander, preadmission, and hospital. Patient-bystander factors are those that prevent immediate medical care through the emergency medical service (EMS) system. Median delays range from 2 to 6.5 hours; in fact, 26 to 44% of AMI patients delay more than 4 hours before seeking medical care. In all major studies evaluating patients’ delay, the median time of arrival at hospital is delayed well beyond the critical first hour during the time period in which half of AMI deaths occur.

Preadmission delay factors occur from the time the patient decides to seek medical attention until the patient arrives at the ED. It is not uncommon for patients to call their primary care physician, which may delay definitive care significantly. Only half of patients with suspected AMI call the EMS system. Many transport themselves or wait for someone other than EMS personnel to take them to the hospital. Further complicating preadmission issues include wide variations in the availability and ability of EMS throughout the United States.

Further delays can occur between the time a patient arrives at the hospital and the initiation of acute revascularization therapy. Overall, the average time to fibrinolysis ranges from 45 to 90 minutes. The GUSTO trial demonstrated a median time from hospital arrival to treatment with fibrinolytic therapy of 70 minutes.128 The AHA recommends that all patients with AMI receive fibrinolytic therapy within 30 minutes of arrival. Ideally, AMI patients who undergo primary PCI should have therapy initiated no later than 90 minutes after arrival.7 STEMI patients who receive hospital-based reperfusion therapies (fibrinolytic agent or PCI) progress through a sequence of steps that can define process time points (Fig. 76-24). Within each interval, various impediments to timely care can occur. Reducing delay times is applicable to all time points in the ED by addressing the four D’s: door (events prior to arrival at the ED), data (obtaining the ECG), decision (arriving at the AMI diagnosis and deciding upon therapy), and “drug” (administering the fibrinolytic agent or passing the angioplasty catheter across the culprit lesion for PCI candidates).

Preadmission care providers may alert the ED to the impending arrival of a patient with a suspected AMI. A field 12-lead ECG may assist in diagnosis and decrease the reperfusion time. Self-transported patients with possible ACS should be evaluated by the triage nurse immediately. Development of hospital-based protocols and system response plans for identifying and rapidly treating patients reduces the amount of time to treatment. When using fibrinolysis in uncomplicated cases, the emergency physician should activate the hospital-based system for reperfusion. Checklists of inclusion and exclusion criteria for fibrinolytic therapy should be available. Fibrinolytic agents should be stored and administered in the ED. Nonconsultative communications prior to administration of the agent with family physicians, internists, or cardiologists may result in unnecessary delays. Medical consultative discussions prior to administration of therapy are warranted in complicated situations. In a system where fibrinolysis is the sole reperfusion therapy, the decision to administer is that of the emergency physician. In a system where the reperfusion strategy can involve either fibrinolysis or PCI, extremely rapid consultation with the treating cardiologist is ideal.

If the hospital offers primary PCI, many hospitals activate “STEMI alert” responses with an ST segment elevation AMI patient. Analogous to the “trauma alert,” the cardiologist and catheterization laboratory personnel are immediately mobilized. Emergency physician activation of the catheterization laboratory demonstrates very high rates of accurate STEMI diagnosis with very low rates of false activation (i.e., the
STEMI mimicker) while markedly reducing the time to definitive therapy. Interhospital transfer of AMI patients for PCI, when they are also candidates for fibrinolysis, should be discouraged if definitive therapy (i.e., catheter placement across the culprit lesion) is likely to be delayed beyond 90 minutes.

**Pharmacologic Intervention**

**Nitroglycerin**

Nitrates decrease myocardial preload and, to a lesser extent, afterload. Nitrates increase venous capacitance and induce venous pooling, which decreases preload and myocardial oxygen demand. Direct vasodilation of coronary arteries may increase collateral blood flow to ischemic myocardium. Most studies of intravenous NTG in the setting of AMI are from the pre fibrinolytic era. A meta-analysis of multiple small trials noted a 35% mortality reduction with intravenous NTG.

Patients with possible ACS and a systolic blood pressure greater than 90 mm Hg should receive a sublingual NTG tablet (0.4 mg or 400 µg) on presentation. If symptoms are not fully relieved with three sublingual tablets, intravenous NTG should be considered. With bradycardia, hypotension, inferior wall AMI, and right ventricular infarction, a sudden decrease in preload associated with NTG can result in profound hypotension. Initial infusion rates at 10 µg/min are titrated to pain symptoms. The clinician should increase the infusion at regular intervals, allowing a 10% reduction in the mean arterial pressure if normotensive and a 20 to 30% reduction if hypertensive. Sublingual bolus therapy, the use of additional sublingual NTG in the setting of intravenous NTG infusions, more rapidly increases the serum level of the medication with delivery of 400-µg boluses. Maximal benefit is probably achieved at 200 µg/min, although certain patients may receive additional benefit at higher infusion rates.

**Morphine**

Morphine is a potent opioid analgesic with weak sympathetic blockade, systemic histamine release, and anxiolysis. If a patient with possible ACS is unresponsive to NTG or has recurrent symptoms despite maximal anti-ischemic therapy, administration of morphine sulfate is appropriate. The relief of pain and anxiety decreases oxygen consumption and myocardial work. Some vasodilatory effects are also noted with preload reduction. Standard doses of morphine sulfate are 2 to 5 mg delivered intravenously, repeated every 5 to 30 minutes as necessary. In addition to allergic reactions, the most significant adverse effect of morphine sulfate administration is hypotension, which is managed with intravenous fluid in bolus fashion.

Caution must be exercised with the administration of morphine in the ACS setting. A review notes an increase in the adjusted risk of death in chest pain patients suspected of ACS who received morphine. This increased risk of mortality was noted in all patients who received morphine as well as in patients who received morphine versus NTG. While one study should not alter the standard medical approach, this must be given consideration.

**Beta-Adrenergic Blockers**

Historically, beta-adrenergic blocking agents have been effective in ameliorating catecholamine-induced tachycardia, including ventricular fibrillation, increased contractility, and heightened myocardial oxygen demand. Beta-blockade is effective in decreasing mortality for patients with AMI. Although the impact of beta-adrenergic blockade in treating UA is less well studied, a meta-analysis showed a 13% reduction in the risk of subsequent AMI.

These observations occurred, however, when adjunctive therapies were few, and beta-adrenergic blockade was monotherapy in AMI. Current management strategies include highly effective reperfusion therapies coupled with potent anticoagulant and antiplatelet agents.

Two large reports suggest that the intravenous use of beta-adrenergic blockade should be reconsidered. The GUSTO-I trial involved fibrinolytic agents for STEMI followed by early intravenous atenolol. The use of the early intravenous beta-adrenergic blocking agents in this study was associated with increased death, heart failure, shock, recurrent ischemia, and pacemaker use than when patients received early oral administration. This occurred despite exclusion of patients with obvious contraindication, including preexisting hypotension, bradycardia, or heart failure. The Clopidogrel and Metoprolol in Myocardial Infarction Trial (COMMIT) evaluated approximately 46,000 patients with suspected STEMI, comparing early intravenous beta-adrenergic blocking agent use...
The GPI is another potent antiplatelet agent. Its use in ACS is determined by the primary indication regarding reperfusion; they noted similar rates of direct outcome measures or secondary markers of successful reperfusion, and hemorrhagic complications are increased.142,143 None of the GPIs has demonstrated significant benefit in the treatment of ACS patients without PCI.144 The Integринl to Manage Platelet Aggregation to Combat Thrombus in Acute Myocardial Infarction (IMPACT-AMI) investigators145 reported the results in AMI patients receiving fibrinolytic agents and varying doses of eptifibatide (i.e., nonmechanical means of reperfusion); they noted similar rates of death, recurrent MI, and the need for revascularization procedures but observed an increase in TIMI grade 3 flow at 90 minutes. Furthermore, using troponin values as an estimate of infarct size, investigators did not demonstrate benefit in eptifibatide-treated patients with non-ST elevation ACS presentations.146

GPI therapy, in the invasively managed patient, continues to offer improved outcome.147,148 In one large series, patients...
who received GPs experienced lower in-hospital mortality (3 vs. 6.2%), which was noted in all STEMI risk groups managed.\textsuperscript{145} Subsequent analysis of the subgroup of patients receiving stents during PCI noted both a lower mortality rate (10.9 vs. 14.3%) and a lower reinfarction rate (2.3 vs. 5.5%) in the treatment group; also, the composite endpoint (death and reinfarction) occurred much less frequently in the treatment group, with a relative risk reduction of 37%. In a large meta-analysis of similar construction, major bleeding was not significantly different.\textsuperscript{148}

The issue of timing and location of GPI administration has recently been explored, with initial studies suggesting that early therapy in the ED is associated with more favorable outcomes.\textsuperscript{149,150} Both of these studies are rather small and thus should not dictate management policy, yet their findings suggest that earlier therapy is “better” with no increased rate of adverse effect.

The glycoprotein IIb/IIIa receptor inhibitors have consistently demonstrated benefit in ACS patients treated with urgent mechanical revascularization; other groups of ACS patients, such as medically managed, combination fibrinolytic agent, or transferred patients, have not established an invariant positive effect. Consequently, the ACC/AHA has provided the following guidelines for GPI use in ACS patients:

1. For patients in whom an initial invasive strategy is selected, additional antiplatelet therapy beyond aspirin should be initiated before PCI with either clopidogrel or GPI (abximab)—only if there is no anticipated, significant delay to coronary angiography and PCI is most likely to be performed. If a significant delay is anticipated to PCI in the invasively managed patient, either eptifibatide or tirofiban is the preferred GPI (class I).
2. For patients in whom an initial noninvasive strategy is selected, it may be reasonable to add eptifibatide or tirofiban to existing antiplatelet and oral antiplatelet therapies (class Ib). GPI (abximab), however, should not be administered to patients in whom PCI (initial invasive strategy) is not planned (class III).
3. For patients in whom an initial noninvasive strategy is selected and who have recurrent ischemia, develop acute heart failure, or experience malignant dysrhythmias while receiving clopidogrel, ASA, and antiplatelet therapy, it is reasonable to add a GPI (eptifibatide or tirofiban) before diagnostic angiography (class I).\textsuperscript{6}

**Thienopyridine Antiplatelet Agents.** The thienopyridines, ticlopidine and clopidogrel, are more potent platelet inhibitors than aspirin. The thienopyridines inhibit the transformation of the glycoprotein IIb/IIIa receptor into its high-affinity ligand-binding state, irreversibly inhibiting platelet aggregation for the duration of the life of the platelet. Ticlopidine has nonlinear kinetics and, after repeated dosing, reaches a maximal effect after 8 to 11 days of dosage. Clopidogrel, a ticlopidine analogue, has the advantages of a rapid onset of action and an intravenous route of administration.

Clopidogrel is the preferred agent of this class because of its more rapid onset of action and its safety profile. Ticlopidine is associated with a risk of neutropenia and agranulocytosis that is not encountered with clopidogrel; furthermore, it demonstrates a much slower onset of platelet inhibition. With clopidogrel, maximal platelet inhibition occurs after 3 to 5 days of clopidogrel therapy using 75 mg daily; an earlier onset of platelet inhibition is seen when a higher loading dose is used (300 to 600 mg). In fact, higher clopidogrel “loading doses” may produce benefit at an earlier time. For instance, there is clear benefit to clopidogrel administration (300-mg loading dose) occurring at least 6 hours before PCI in patients with STEMI; higher doses (e.g., 600 mg) in many studies demonstrate a trend toward improvement at slightly earlier time periods (i.e., 3 to 4 hours).

From the emergency medicine perspective, the most appropriate recommendation for clopidogrel in the ED is the patient with a high-risk ACS presentation who is truly allergic to ASA (ACC/AHA class I indication);\textsuperscript{151} this high-risk presentation would be characterized by objective clinical abnormality, including a significantly abnormal serum marker and/or 12-lead ECG. Other indications are discussed below.

The considerations which must be kept in mind include the ultimate treatment strategy chosen (i.e., medical versus invasive) and the time to angiography if an invasive plan is elected. ACS patients managed medically (i.e., noninvasively) or invasively with coronary angiography deferred to a later time are the most appropriate, potential candidates for clopidogrel.\textsuperscript{151–154} In the patient selected for invasive management, the time-to-the-procedure must be considered as a primary issue when considering clopidogrel—patients undergoing early angiography (less than 6 hours) are less likely to derive significant benefit, while deferred catheterization likely will gain advantage as a result of this treatment.

In the patient with unstable angina or NSTEMI, clinical benefit is confirmed in UA patients when treated with clopidogrel in a noninvasive strategy scenario, with an increase in major hemorrhage.\textsuperscript{155} As noted, invasively managed patients receiving the drug with less time to procedure performance do not benefit from such treatment. The NSTEMI patient demonstrates improved outcome with clopidogrel therapy when a conservative treatment scenario is initially followed.\textsuperscript{155} Of note, a large portion of these patients will undergo PCI within the first 24 hours after admission; yet, this “delayed” PCI allows for benefit to occur from clopidogrel administered earlier in the course of management.

The STEMI patient who is managed medically (i.e., with a fibrinolytic agent) will also benefit from clopidogrel use. Clopidogrel therapy in conjunction with fibrinolysis followed by deferred cardiac catheterization occurring at least 2 days post-AMI—clearly beyond this 6-hour window—decreases the rates of death, recurrent ACS, and urgent coronary revascularization. This improvement occurs without a significant increase in hemorrhage.\textsuperscript{154} Conversely, the use of clopidogrel does not appear to show benefit in the STEMI patient if the drug is given less than 6 hours prior to PCI performance, regardless of the clinical setting.

ACS (UA, NSTEMI, and STEMI) patients with PCI performed soon after arrival (i.e., less than the 6-hour interval from clopidogrel dosing) are less likely to benefit from early therapy. Thus, urgent PCI for the ACS patient is not associated with significant clopidogrel-derived clinical advantage. ACS patients urgently or emergently managed with PCI are less likely to benefit from clopidogrel use in the ED.

The potential need for urgent CABG must also be strongly considered. The higher risk ACS patient will more likely benefit from clopidogrel therapy, yet the same patient will more likely need urgent CABG. The emergency physician, however, is not able to reliably identify ACS patients requiring urgent CABG. Of the 60,000 patients in the CRUSADE registry, 14% underwent CABG, a reasonably frequent rate of surgical intervention;\textsuperscript{156} most centers, however, report a 2 to 5% incidence of coronary surgery. Mehta and colleagues, in a review of ED ACS patients, were unable to demonstrate a single or combination of clinical features that reliably identified patients not requiring CABG.\textsuperscript{157} Interestingly, an analysis of the CURE database suggests that, while these CABG patients had a greater incidence of bleeding perioperatively,
outcomes were not statistically different in clopidogrel versus placebo groups in this surgical subset. It is likely that as the cardiovascular surgeon gains more experience with clopidogrel, this concern will cause less anxiety, much like ASA and heparin in years past.

The ACC/AHA suggests—in the form of a Class I recommendation—that clopidogrel should be withheld for at least 5 days before CAGB. If CAGB is performed within 5 days of clopidogrel use, patients have an increased incidence of operative and postoperative hemorrhage, increased need for transfusions, increased need for re-operation for hemostasis, and increased postoperative mortality. Nevertheless, the recommendation suggests that early clopidogrel therapy should be considered in those patients who likely will not require CAGB. The American College of Emergency Physicians Clinical Policy concludes that there is insufficient evidence to recommend any exact location or timing of clopidogrel administration in the ACS patient. In that it does not appear possible for the emergency physician to reliably predict which patients will require urgent CABG, collaborative multidisciplinary pathways should be developed, with emergency medicine, cardiologist, and cardiovascular surgeons providing input.

Antithrombins

As with antiplatelet therapies in ACS patients, significant reductions in the progression to acute, recurrent, or extensive infarction and death are noted in individuals treated with aggressive antithrombin therapy. The antithrombins include unfractionated heparin, low-molecular-weight (fractionated) heparin (LMWH), and the direct thrombin inhibitors (hirudin and bivalirudin). Antithrombotic therapy is indicated in ACS patients with recurrent anginal pain, AMI (non-ST segment elevation and ST segment elevation), positive serum marker, and a dynamic 12-lead ECG.

**Heparins.** The term heparin refers not to a single structure but rather to a family of mucopolysaccharide chains of varying lengths and composition—hence, unfractionated—with pronounced antithrombotic properties. At standard doses, unfractionated heparin binds to antithrombin III, forming a complex that is able to inactivate factor II (thrombin) and activated factor X. This prevents the conversion of fibrinogen to fibrin, thus preventing clot formation. Heparin by itself has no anticoagulant property. This indirect effect on thrombin inhibits clot propagation; it prevents heparin, however, from having any effect on bound thrombin in a thrombus. Unfractionated heparin also assists in the inactivation of factors Xa and Xa through antithrombin and interacts with platelets.

Unfractionated heparin has a profound synergistic effect with aspirin in preventing death, AMI, and refractory angina in ACS patients, particularly those with AMI and, to a lesser extent, high-risk UA. Unfractionated heparin should be administered early in patients with the following ACS features: recurrent or persistent chest pain, AMI, positive serum marker, and dynamic ECG. In patients undergoing PCI, bleeding and mortality were higher in TIMI 14 in patients receiving an 80-U/kg bolus and 18-U/kg infusion compared to patients with lower bolus amount and infusion rate. Therefore, the weight-adjusted regimen recommended is an initial bolus of 60 U/kg (maximum 4000 U) and an initial infusion of 12 U/kg/hr. The activated partial thromboplastin time should be titrated to 1.5 to 2.5 times the control value.

LMW heparins constitute approximately one third of the molecular weight of heparin and are less heterogeneous in size. The LMW heparins inhibit the coagulation system in a fashion similar to that of unfractionated heparin. Approximately one third of the heparin molecules bind to both antithrombin III and thrombin. The remaining molecules bind only to factor Xa. The variable efficacy found among the LMW heparins is attributed to different ratios of antifactor Xa to antifactor IIa. High-ratio preparations have a clear advantage over standard heparin; enoxaparin has the highest ratio of available LMW heparins. LMWH was designed on the basis of the hypothesis that inhibition of earlier steps in the blood coagulation system would be associated with a more potent antithrombotic effect than inhibition of subsequent steps. This results from the amplification process inherent in the coagulation cascade; that is, a single factor Xa molecule can lead to the generation of multiple thrombin molecules.

Potential advantages of LMW heparin over unfractionated heparin include easier administration, greater bioavailability, more consistent therapeutic response among patients, longer serum half-life producing a more manageable dosing schedule, and reduced rates of adverse bleeding episodes, albeit at a higher cost.

The combination of aspirin, beta-blocker, and LMWH (dalteparin) significantly decreases the rate of nonfatal AMI or death at 1 week of therapy with a less pronounced effect at 40 to 150 days, but with an increase in minor bleeding episodes.

Studies comparing outcomes between LMWH and unfractionated heparin have shown mixed results, with some showing better outcomes with LMWH while others do not. In summary, the LMWH enoxaparin demonstrates some degree of benefit compared to unfractionated heparin (UFH) in higher-risk NSTE-ACS patients treated conservatively without immediate PCI (i.e., beyond 24 hours). Conversely, in patients managed aggressively with PCI within 24 hours, enoxaparin offers little benefit while major bleeding rates are increased.

Enoxaparin is administered in a twice-daily regimen subcutaneously at a dose of 1 mg/kg. If patients have renal dysfunction with an estimated glomerular filtration rate less than 30 mL/min, the dose should be reduced to 1 mg/kg in a single daily administration. There are little safety data available for enoxaparin in ACS patients with renal insufficiency, and UFH may be preferable.

Contraindications to heparin therapy include known allergy, active ongoing hemorrhage, and predisposition to such hemorrhage. Further, patients who have their heparin therapy changed (UFH to LMWH and vice versa) during the active treatment phase of their ACS care experience higher rates of bleeding.

The vast majority of patients with AMI require therapy with heparin, whether it is fractionated or unfractionated. Non-AMI ACS, however, is an entirely different issue since UA is a heterogeneous condition. For example, the stable patient with a classical description of new-onset angina who is sensation free with a negative serum marker and a normal ECG is still correctly diagnosed with UA. In contrast, an individual who presents with ongoing pain, either intermittent or constant, with a dynamic ECG clearly represents an active, unstable coronary event. The latter patient, who is at higher risk, can benefit from heparin therapy more than the former. Heparin therapy, however, can be a major contributor to morbidity and mortality among hospitalized patients. Major bleeding develops in 1 of every 90 patients treated, and heparin-induced thrombocytopenia in 1 of 34 patients. LMWH is as effective as unfractionated heparin in patients with ACS and does not greatly increase the bleeding risk while decreasing the risk of thrombocytopenia.

**Other Antithrombins (Hirudin, Bivalirudin, and Fondaparinux).** The direct thrombin inhibitors hirudin and bivalirudin (formerly known as hirulog) are potent antithrombin anticoagulants providing significant theoretical advantages compared with heparin. Hirudin is a peptide derived from the leech salivary gland but is also synthesized as recombinant hirudin. It binds directly
with high affinity to thrombin and can inactivate thrombin already bound to fibrin (clot-bound thrombin) more effectively than UFH. Hirudin does not require endogenous cofactors such as antithrombin III for its activity. Also, unlike heparin, hirudin can inhibit thrombin-induced platelet aggregation. Hirudin demonstrates little significant benefit over other anticoagulants in ACS, with a possible increased rate of hemorrhage; thus, it offers little value in the ACS patient.

Bivalirudin is a bifunctional 20–amino acid peptide designed on the basis of the structure of hirudin. It has properties similar to those of hirudin but also interacts with the catalytic site of thrombin. Bivalirudin, however, is more effective than heparin in reducing death or reinfarction in patients with ACS, particularly in those patients undergoing very early PCI.164

Bivalirudin compared with heparin produces similar rates of ischemia and major bleeding at 1 month. Bivalirudin when used with clopidogrel is comparable to the combination of heparin and GPI prior to coronary angiography or PCI. When used alone, it is inferior to the combination of heparin and GPI.165 Bivalirudin should be considered an acceptable alternative anticoagulant agent compared to the heparins in the ACS patient, and has a class I indication for the ACS patient.6

Fondaparinux is a synthetic oligosaccharide with a structure similar to the heparins. It is the first widely used selective factor Xa inhibitor. As with the other ACS anticoagulant agents, fondaparinux has a class I ACC/AHA recommendation.7 With the increased emphasis on the reduction of hemorrhagic complications in ACS care, this drug appears to demonstrate similar efficacy to LMWH with fewer bleeding complications. The attendant reduction in mortality appears to be almost entirely explained by decreased bleeding complications, including patients selected for PCI, renal failure patients, and patients receiving other anticoagulation, including UFH.166,167 Thus, when either invasive or noninvasive strategies are contemplated, fondaparinux is an effective anticoagulant for the ACS patient. It also may be ideal for the patient with significant renal dysfunction or at increased risk of hemorrhage. The dose is 2.5 mg subcutaneously once daily for all patients.

In the large Optimal Antiplatelet Strategy for Interventions (OASIS) trial, fondaparinux is similar to enoxaparin in the short-term reduction of ischemic events, yet substantially reduces major bleeding and improves long-term outcome.166 The OASIS-6 investigators reviewed the use of fondaparinux in 5436 STEMI patients managed medically with fibrinolytic agents. Fondaparinux significantly reduced hemorrhage and the primary study outcome (death or myocardial infarction) as well as the individual occurrence of these endpoints at 30 days.167

Reperfusion Therapies

Reestablishing perfusion in the infarct-related coronary artery with the use of fibrinolytic therapy or PCI increases the opportunity for salvage of the ischemic myocardium. Pharmacologic and mechanical methods of reperfusion are both effective under specific clinical conditions. The importance of early coronary artery patency was affirmed by the GUSTO investigators in their angiographic substudy. They demonstrated that 90-minute patency predicts rates of survival and preserves left ventricular function more than in those patients not achieving normal coronary flow.128

Fibrinolytic therapy unequivocally improves survival in patients presenting with STEMI and remains an ACC/AHA class I recommendation.7 Although fibrinolysis has widespread availability and a proven ability to improve coronary flow, limit infarct size, and improve survival in AMI patients, many individuals with acute infarction are not suitable candidates. Patients with absolute contraindications to fibrinolytic therapy, certain relative contraindications, cardiogenic shock, and UA may not be eligible. The temporal constraints and other limitations of fibrinolytic therapy suggest that rapidly performed PCI is often the treatment of choice in the STEMI patient. To provide the most significant benefit, PCI must be performed as soon as possible after the initial presentation. In other settings and situations, PCI that is delayed is inferior to rapidly administered fibrinolysis.

Fibrinolytic Therapy

Fibrinolytic Agent Selection. Three megatrails compared tissue-type plasminogen activator (t-PA) with streptokinase. The Gruppo Italiano per lo Studio della Streptochinasi nell’Infarto Miocardico (GISSI-2) trial168 and the closely related International Study169 compared a 100-mg infusion of t-PA over 3 hours with streptokinase with or without heparin. The GISSI-2 study was the first large-scale mortality trial directly comparing t-PA and streptokinase in patients with AMI. The investigators found no difference in mortality between the two treatment groups. More strokes were reported with t-PA than with streptokinase (1.3 vs. 1%) in the International Study, yet the frequency of confirmed hemorrhagic stroke was similar for both agents. Similar results were found in the ISIS-3 study,170 the next fibrinolytic megatrial, which compared t-PA, streptokinase, and anisoylated plasminogen-streptokinase activator complex in approximately 40,000 patients. In marked contrast to current practice, the inclusion criteria allowed entry up to 24 hours after symptom onset and did not require diagnostic electrocardiographic change. All patients received adjunctive aspirin therapy, and approximately half of the patients were given delayed, unmonitored subcutaneous heparin. A significant difference in both 35-day mortality and intracranial hemorrhage was not found. The results of the ISIS-3 study,170 proved controversial because of the unmonitored, delayed subcutaneous heparin protocol, particularly with studies now proving improved infarct artery patency using early therapeutic intravenous doses of heparin.

Current fibrinolytic practice is highly affected by the results of the GUSTO-I trial.128 The purpose of the GUSTO-I trial was to test the hypothesis that early and sustained infarct vessel patency was associated with better survival rates in patients with AMI.128 More than 41,000 patients were randomly assigned to four different fibrinolytic strategies: accelerated t-PA given over 90 minutes plus intravenous heparin, a combination of streptokinase plus a reduced dose of t-PA along with intravenous heparin, and two control groups (streptokinase plus subcutaneous heparin and streptokinase plus intravenous heparin). Unlike previous trials, t-PA was given in a more aggressive, front-loaded 90-minute infusion (referred to as accelerated t-PA). In addition to a primary endpoint of 30-day mortality, the GUSTO investigators explored coronary artery patency and degree of normalization of flow in the angiographic substudy. This portion of the larger trial was designed to determine the relationship between early coronary artery patency and outcome. In this trial, accelerated t-PA, administered with intravenous heparin, reduced 30-day mortality significantly by 15% compared with streptokinase with either form of heparin or the combination of t-PA and streptokinase with intravenous heparin. The benefit was highly consistent across virtually all subgroups, including elderly patients, location of AMI, and time from symptom onset. These differences remained significant at 1 year of follow-up.

The angiographic substudy demonstrated a strong relationship between TIMI flow and outcome. Patients with strong forward flow (i.e., TIMI grade 3 flow) at 90 minutes had significantly lower mortality rates than patients with little to no
II
Section three

No evidence of benefit from fibrinolytic therapy is found in contiguity ICH.172 In a subgroup analysis, however, significantly lower 30-day mortality was noted among patients who presented more than 4 hours after onset of symptoms—a significant number of patients in many institutions. In this group of patients, accelerated t-PA may be superior to r-PA because of its greater fibrin specificity.171

The Assessment of the Safety and Efficacy of a New Thrombolytic Agent (ASSENT-2) trial investigated the use of TNK, another mutant of wild-type t-PA. TNK has several potential benefits: (1) its longer half-life allows it to be administered as a single bolus, (2) it is 14 times more fibrin specific than t-PA and even more so than r-PA, and (3) it is 80 times more resistant to plasminogen activator inhibitor type 1 than t-PA. The ASSENT-2 trial172 randomly assigned approximately 17,000 patients with AMI to single-bolus TNK (30–50 mg on the basis of body weight) or accelerated t-PA (100 mg total infusion). The investigators found no differences in mortality or ICH.172 In a subgroup analysis, however, significantly lower 30-day mortality was noted among patients who presented more than 4 hours after onset of symptoms in those treated with TNK. Further, fewer noninfracentral major bleeding episodes were encountered in the TNK group. On the basis of these results, it is concluded that TNK is equally or minimally more effective, particularly in late presenters. Concerning adverse reactions, TNK also appears modestly safer than accelerated t-PA. Lastly, because of its single-bolus administration, TNK is markedly easier to use in preadmission environments and the ED.

Eligibility Criteria for Fibrinolytic Agent Therapy

The 12-Lead Electrocardiogram. Combined with the patient’s history and physical examination, the 12-lead ECG is the key determinant of eligibility for fibrinolysis. The electrocardiographic findings include two basic issues: (1) ST segment elevation of 1 mm or more in two or more anatomically contiguous standard limb leads and elevation of 2 mm or more in two or more contiguous precordial leads, and (2) new or presumed new LBBB.

No evidence of benefit from fibrinolytic therapy is found in patients with ischemic chest pain who lack either appropriate ST segment elevation or the new development of LBBB.7

Patients with LBBB and AMI are at an increased risk for a poor outcome and need rapid reperfusion therapy. The new development of LBBB in the setting of AMI suggests proximal occlusion of the left anterior descending artery and places a significant portion of the left ventricle in ischemic jeopardy. Unfortunately, patients with LBBB receive fibrinolytic agents less often than those with the more electrocardiographically alarming STEMI.

Patients with AMI in anterior, inferior, or lateral anatomic locations benefit from fibrinolytic therapy. The relatively favorable prognosis associated with inferior infarction without fibrinolytic therapy requires larger sample sizes to detect a significant survival benefit. The ISIS-2 trial173 demonstrated a statistically significant mortality benefit for fibrinolytic therapy in patients with inferior AMI. Patients with inferior AMI with coexisting right ventricular infarction, as detected by additional lead ECGs, are likely to benefit because of the large amount of jeopardized myocardium. Acute, isolated posterior wall MI, diagnosed by posterior leads, may be another electrocardiographic indication for fibrinolysis. Although unproven in large fibrinolytic agent trials, patients with isolated posterior AMI may be considered for reperfusion therapy.

Fibrinolytic therapy should not be used routinely in patients with only ST segment depression on the 12-lead ECG, and the mortality rate may actually be increased. The TIMI-3 trial174 demonstrated a significant difference in outcome in fibrinolytic-treated patients with only ST segment depression—7.4% incidence of death compared with 4.9% in the placebo group. These findings are further supported in the Fibrinolytic Therapy Trialists’ (FTT) meta-analysis, which demonstrated that the mortality rate among patients with ST segment depression who received fibrinolytic therapy was 15.2% compared with 13.8% among control subjects.175

Patient’s Age. Past trials do not provide evidence to support withholding fibrinolytic therapy or choosing one particular agent over another on the basis of the patient’s age. In fact, the FTT Collaborative Group175 concluded that “clearly, age alone should no longer be considered a contraindication to fibrinolytic therapy.” Patients older than 75 years do have a higher incidence of hemorrhagic stroke than younger patients.

Time from Symptom Onset. The generally accepted therapeutic time window for administration of a fibrinolytic agent after the onset of ST segment elevation AMI is 12 hours. Patients treated within the first 6 hours of AMI have the best outcome. Later administrations, from 6 to 12 hours after AMI onset, also confer benefit, although of a lesser magnitude. The Late Assessment of Fibrinolytic Efficiency (LATE) trial, which compared fibrinolytic therapy with placebo, found a significant 26% decrease in 35-day mortality in patients treated with t-PA, heparin, and aspirin 6 to 12 hours after the onset of symptoms.176 There was no significant decrease in mortality among patients treated 12 to 24 hours after symptom onset.

These studies clearly establish benefit from 0 to 12 hours in patients who are otherwise appropriate candidates for fibrinolytic therapy. Treatment beyond that time is not supported by the literature. The single exception may be a patient with a “stuttering” nature of chest pain between 12 to 24 hours after symptom onset, which emphasizes the importance of an adequate history.

Blood Pressure Extremes. Patients with a history of chronic hypertension should not be excluded from fibrinolytic therapy if their blood pressure is under control at the time of presentation or can be lowered to acceptable levels using standard therapy for ischemic chest pain. The admission blood pressure is also an important indicator of risk of intracerebral hemorrhage. The FTT meta-analysis175 demonstrated that the risk of cerebral hemorrhage increases with systolic blood pressure greater than 150 mm Hg on admission and further increases when systolic blood pressure is 175 mm Hg or higher. Despite an increased mortality rate during days 0 and 1, the FTT meta-analysis demonstrated an overall long-term benefit of 15 lives saved per 1000 for patients with systolic blood pressures greater than 150 mm Hg and 11 lives saved per 1000 for patients with systolic blood pressures of 175 mm Hg or greater.175 Although the FTT meta-analysis appears to indicate an acceptable risk-benefit ratio for patients with substantially increased systolic blood pressure, a persistently elevated blood pressure greater than 200/120 mm Hg is generally
considered to be an absolute contraindication to fibrinolytic therapy.

The benefit of fibrinolytic therapy in patients with hypotension is unclear. The GISSI-1 and GISSI-2 trials showed no apparent reduction of mortality rate with fibrinolytic therapy among patients classified in Killip class III or IV. These findings have led to the suggestion that primary angioplasty, not fibrinolytic therapy, be used in patients with cardiogenic shock. The FTT meta-analysis, however, does not support this hypothesis. In this meta-analysis, patients with an initial systolic blood pressure less than 100 mm Hg who were not treated with fibrinolytic therapy had a very high risk of death (35.1%), and those who were treated with fibrinolytic therapy had the largest absolute benefit (60 lives saved per 1000 patients). On the basis of this evidence, the FTT Collaborative Group suggested that hypotension, heart failure, and perhaps even shock should not be contraindications to fibrinolytic therapy. These data support immediate treatment followed by diagnostic angiography and further intervention as indicated.

Retinopathy. Active diabetic hemorrhagic retinopathy is a strong relative contraindication to fibrinolytic therapy because of the potential for permanent blindness caused by intraocular bleeding. There is no reason, however, to withhold the use of a fibrinolytic agent in a diabetic patient with evidence of simple background retinopathy. Patients with diabetes mellitus who sustain an AMI have an almost doubled incidence of mortality.

Cardiopulmonary Resuscitation. CPR is not a contraindication to fibrinolytic therapy unless CPR has been prolonged—more than 10 minutes—or extensive chest trauma from manual compression is evident. Although the in-hospital mortality rate is higher in AMI patients who experience cardiac arrest and then receive fibrinolytic agents in the ED, no difference is found in the rates of bleeding complications. Hemotorax and cardiac tamponade were not diagnosed in those receiving fibrinolytics who survived to admission. Even prolonged CPR beyond 10 minutes does not appear to be associated with higher rates of complication.

Previous Stroke or Transient Ischemic Attack. A history of previous stroke or transient ischemic attack is a major risk factor for hemorrhagic stroke after treatment with fibrinolytic therapy. A history of previous ischemic stroke should remain a strong relative contraindication to fibrinolytic therapy, and previous hemorrhagic stroke an absolute contraindication.

Previous Myocardial Infarction or Past Coronary Artery Bypass Graft. In the setting of AMI, a previous MI should not preclude consideration for treatment with fibrinolytic agents. Without treatment, there is a potential for greater loss of function in the newly infarcting region of the myocardium. Although the GISSI-1 trial showed no treatment benefits for patients with previous MIs, the ISIS-2 trial demonstrated a 26% relative mortality rate reduction. The FTT meta-analysis further demonstrated that patients with a history of past MI who receive fibrinolytic therapy for recurrent acute infarction have a mortality rate of 12.5% compared with 14.1% among control patients.

Many studies report successful fibrinolysis in AMI patients with a prior CABG. Complete thrombotic occlusion of the bypass graft is the cause of AMI in approximately 75% of cases as opposed to native vessel occlusion. Because of the large mass of thrombus and absent flow in the graft, conventional fibrinolytic therapy may be inadequate to restore flow. These patients should be considered for direct angioplasty or combined fibrinolysis and rescue angioplasty.

Recent Surgery or Trauma. Recent surgery or trauma is considered a relative contraindication to fibrinolytic therapy. The term recent is subject to variable interpretation in fibrinolytic trials. In the GISSI-1 trial, patients were excluded if they had surgery or trauma within the previous 10 days. In the Anglo-Scandinavian Study of Early Thrombolysis (ASSET) trial, patients were excluded for surgery or trauma within the previous 6 weeks. Other fibrinolytic therapy trials do not define “recent surgery or trauma.” Alternative interventions should be considered in patients with AMI within 10 days of surgery or significant trauma.

Menstruation. Since natural estrogen is partially cardioprotective, there is little experience with fibrinolysis among premenopausal women. Gynecologists indicate that any excessive vaginal bleeding that may occur after receiving fibrinolytic therapy should be readily controllable by vaginal packing and therefore can be considered as a compressible site of bleeding.

Contraindications. A list of absolute and relative contraindications is shown in Box 76-1.

Percutaneous Coronary Intervention

Although fibrinolysis has widespread availability and a proven ability to improve coronary flow, limit infarct size, and improve survival in AMI patients, many individuals with acute infarction are not considered suitable candidates. Patients with absolute contraindications to fibrinolytic therapy, certain relative contraindications, cardiogenic shock, and UA may be ineligible to receive fibrinolytic therapy. The requirement of administering prompt reperfusion therapy to these patients, as well as the other limitations of fibrinolytic therapy, have led many clinicians to advocate PCI. PCI has many theoretical advantages over fibrinolysis, including an increased number of
eligible patients, a lower risk of intracranial bleeding, a significantly higher initial reperfusion rate, an earlier definition of coronary with rapid triage to surgical intervention, and risk stratification allowing safe, early hospital discharge. Potential disadvantages include operator expertise and numerous catheterization laboratory logistical issues, including local and regional availability as well as time to therapy application.

Several trials of varying sizes comparing primary PCI with fibrinolysis are reported. Interventions in the early trials were performed prior to the current widespread use of coronary stents with GPI. Despite a clear and consistent benefit of PCI in restoring patency of the infarct-related artery, differences in mortality in the individual trials were difficult to evaluate because of the smaller sample sizes. The Primary Angioplasty in Myocardial Infarction (PAMI) trial enrolled 395 patients randomly assigned to undergo PCI or to receive t-PA. Compared with standard-dose t-PA, PCI reduced the combined occurrence of nonfatal reinfarction or death, was associated with a lower rate of intracranial hemorrhage, and resulted in a similar left ventricular function. The results of the Netherlands trial indicate that primary angioplasty is associated with a higher rate of patency of the infarct-related artery, a less severe residual stenotic lesion, better left ventricular function, and less recurrent myocardial ischemia and infarction than in patients receiving streptokinase.

In a substudy of the GUSTO IIb trial, the investigators randomly assigned 1138 patients with AMI to either PCI or accelerated t-PA. The composite endpoint of the study included death, nonfatal reinfarction, and nonfatal disabling stroke, all occurring within 30 days of the AMI. Of the patients assigned to PCI therapy, 83% were candidates for such treatment and underwent angioplasty 1.9 hours after ED arrival for a total elapsed time from chest pain onset to therapy of 3.8 hours. Ninety-eight percent of the patients assigned to fibrinolytic therapy received t-PA 1.2 hours after hospital arrival. The composite endpoint was encountered significantly less often in the PCI group (9.6%) than in the t-PA group (13.7%) at 30 days. When the individual components of the composite endpoint at 30 days were considered separately, death, infarction, and stroke occurred at statistically similar rates for both treatment groups. A meta-analysis reviewed 10 major studies comparing fibrinolysis with primary PCI in more than 2600 patients. The 30-day mortality and stroke occurrence were significantly lower in the PCI group.

The second Danish acute myocardial infarction (DANAMI-2) trial comprehensively investigated the PCI strategy. Investigators randomly assigned AMI patients to receive either PCI or accelerated t-PA. The composite endpoint of the study included death, nonfatal reinfarction, and nonfatal disabling stroke, all occurring within 30 days of the AMI. Of the patients assigned to PCI therapy, 83% were candidates for such treatment and underwent angioplasty 1.9 hours after ED arrival for a total elapsed time from chest pain onset to therapy of 3.8 hours. Ninety-eight percent of the patients assigned to fibrinolytic therapy received t-PA 1.2 hours after hospital arrival. The composite endpoint was encountered significantly less often in the PCI group (9.6%) than in the t-PA group (13.7%) at 30 days. When the individual components of the composite endpoint at 30 days were considered separately, death, infarction, and stroke occurred at statistically similar rates for both treatment groups. A meta-analysis reviewed 10 major studies comparing fibrinolysis with primary PCI in more than 2600 patients. The 30-day mortality and stroke occurrence were significantly lower in the PCI group.

The Controlled Abciximab and Device Investigation to Lower Late Angioplasty Complications (CADILLAC) investigators compared angioplasty and PCI using coronary stents in STEMI patients undergoing urgent reperfusion therapy; abciximab was added to portions of both treatment groups. At 6 months, the primary endpoint (a composite of death, recurrent infarction, stroke, and urgent revascularization) had occurred in 20% of patients after angioplasty, 17% after PCI with abciximab, 12% after stenting, and 10% after stenting with abciximab.

The longer-term results with PCI, however, are less clear. The GUSTO IIb study showed no overall mortality advantage of PCI at 6 months. Much of the literature comparing the acute reperfusion therapies in AMI does not include the use of coronary stenting during PCI.

The issue of long-term outcome in PCI-managed STEMI patients is further complicated by drug-eluting stents (DES). Early studies used bare metal stents (BMS), which, in the setting of an acute thrombotic event such as STEMI, raised concern regarding stent thrombosis with obstruction and recurrent AMI. A review of this issue compared BMS and DES with both angiographic and clinical outcome variables in STEMI patients treated with PCI using intracoronary stenting. Event-free survival at 12 months was significantly higher in the DES group, with 74% in BMS patients and 86% in DES patients. Furthermore, the target-vessel-failure-free (i.e., correctly functioning culprit artery stent) survival was also significantly greater in the DES patients compared to the BMS group. The rates of death, myocardial infarction, and stent thrombosis, however, were not significantly different between the groups. Also, a higher rate of stent malposition was noted in the DES group, despite a lower rate of event occurrence in this contingent.

A meta-analysis of 7 randomized trials compared the effects of DES and BMS in 2357 AMI patients. This study reported that DES significantly reduces the need for revascularization without changes in death or myocardial infarction out to 1 year follow-up; no increased risk of thrombosis was found in the DES group. Another group extended the follow-up period of patients managed with coronary stenting. This patient group, undergoing PCI with stenting in an elective setting, extended the period of observation out to 2 years. These investigators found that target vessel revascularization was needed less often in the DES group, yet the rates of AMI and death were similar.

Thus, PCI with stenting appears to be superior to standard angioplasty. The addition of DES to the equation has produced less favorable results, however, with similar rates of myocardial infarction and death coupled with a lower rate of revascularization in the DES patients to several years postintervention.

Rescue PCI. Historically, rescue PCI has been considered advantageous in patients whose infarct-related arteries fail to reperfuse after fibrinolytic therapy. These patients are profoundly ill, with a markedly worse outcome. Some centers routinely catheterize patients after fibrinolytic therapy to determine whether successful reperfusion has occurred and to perform angioplasty if feasible. Other centers catheterize patients after fibrinolytic therapy only if there is clinical evidence that the infarct-related artery fails to open, as suggested by continued chest pain or persistent ST segment elevation.

The Middlesbrough Early Revascularization to Limit INfarction (MERLIN) trial compared outcomes after rescue PCI with a conservative management strategy in STEMI patients who fail fibrinolysis. Rescue PCI was not associated with improved survival at 1 month; further, increased rates of stroke and transfusion were noted in this group. At 1- and 3-year intervals, the lack of survivor benefit persisted. In a meta-analysis of STEMI patients who did not achieve satisfactory reperfusion after fibrinolysis, rescue PCI was not associated with mortality reductions. In this very ill group,
however, the incidence of heart failure and recurrent infarction was reduced. Repeat fibrinolysis was not associated with significant improvements in mortality or recurrent infarction.\textsuperscript{193} Although the decision to offer rescue PCI in the failed fibrinolytic patient remains controversial, evidence favors rescue PCI and does not support the use of repeat fibrinolysis. Facilitated PCI refers to the combination therapy involving fibrinolysis with urgent PCI. This concept originally was developed to maximize therapy in STEMI patients who would be transferred urgently for PCI; the patient would receive a fibrinolytic agent prior to transfer, thus optimizing therapy prior to arrival at the PCI-capable institution. Outcomes are less optimal in those patients undergoing facilitated PCI compared to either fibrinolysis or standard PCI. The ASSENT-4 PCI investigators considered this approach with tenecteplase in a facilitated PCI protocol for STEMI patients. The tenecteplase group had a higher rate of the primary endpoint (death, acute CHF, or shock) within 90 days as well as increased occurrences of stroke, ischemic cardiac complications, and need for repeat revascularization.\textsuperscript{194} A larger meta-analysis of 17 trials compared facilitated PCI to standard PCI in the STEMI patient. Patients undergoing facilitated PCI experienced higher rates of poor outcome and complication compared to the standard PCI group. The facilitated PCI group fared less well, with a higher rate of nonfatal recurrent infarction, urgent need for revascularization, major bleeding, and stroke.\textsuperscript{195}

Choice of Reperfusion Therapy

The principal choices for reperfusion therapy in the STEMI patient include fibrinolysis and PCI. Numerous recommendations, statements, guidelines, and protocols exist. Regardless of the reperfusion strategy selected, "... the systems goal should be a first medical contact-to-[therapy] time within 90 minutes."\textsuperscript{7} The following recommendations should be considered by the emergency physician and other involved clinicians in determining the most appropriate reperfusion therapy for the STEMI patient. A fibrin-specific fibrinolytic agent is the preferred strategy in the patient without contraindication to such therapy who presents early in the time course of the infarction (i.e., <3 hours). In this fibrinolytic-preferred strategy, PCI is either not available (i.e., a noninvasive center) or delayed (transfer or other logistical problems). The system goal for fibrinolytic therapy is to deliver the drug within 30 minutes of patient presentation.\textsuperscript{7}

PCI is the preferred reperfusion strategy in the STEMI patient who can arrive in the catheterization laboratory with placement of the catheter adjacent to the culprit artery lesion within 90 minutes of initial hospital arrival.\textsuperscript{7} High-risk STEMI patients, “late presenters” (i.e., >3 hours since the onset of STEMI symptoms), and individuals with contraindication to fibrinolysis are also candidates for PCI. When the diagnosis of STEMI is in doubt, PCI is the most appropriate diagnostic and therapeutic strategy. If applied early without time delay, PCI provides improved outcome over fibrinolysis in the STEMI patient. It must be initiated within 90 minutes of arrival at the initial hospital ED.\textsuperscript{7} As noted in the DANAMI-2 study,\textsuperscript{184} PCI initiated within 3 hours of initial hospital arrival is also superior to fibrinolysis. Since many hospital systems do not have the capability of meeting the time goal for primary PCI, fibrinolytic therapy is preferred because of the critical importance of time to treatment from onset of symptoms of STEMI in reducing morbidity and mortality.\textsuperscript{7}

If the time required to mobilize staff and arrange for PCI is prolonged or delays in transfer are anticipated, the treating physician must consider fibrinolysis. Prior agreement between the ED and the cardiovascular physicians at institutions with invasive capability must be obtained so that PCI consideration does not introduce further delays in fibrinolytic drug administration. Consensus clinical pathways limit additional delays in the administration of fibrinolytic agents in patients who are considered for PCI in AMI.\textsuperscript{196}

An elegant analysis of the “PCI vs. fibrinolysis” consideration in the STEMI patient asks: How long should the practitioner wait for PCI in a patient who is fibrinolytic eligible? Considerations include the important time-to-therapy question and also factors such as the time from onset to presentation, patient age, and infarct location. Time recommendations are also provided with respect to patient age, infarct duration, and MI anatomic location. The maximal elapsed times one should wait for PCI (the actual time to balloon inflation) at which point the survival benefit of the invasive strategy is lost and the patient should receive a fibrinolytic agent are suggested.\textsuperscript{197}

In this complex analysis of 192,509 patients in a national STEMI registry,\textsuperscript{197} a broad range of acceptable PCI “waiting times” range from approximately 40 to 180 minutes. For instance, the relatively younger patient who is experiencing an anterior STEMI and presents within 2 hours of symptom onset should be in the catheterization laboratory with the catheter across the lesion within 40 minutes or receive a fibrinolytic agent. Conversely, the “older” STEMI patient with an inferior or lateral STEMI who presents beyond 2 hours of symptom onset could wait up to 179 minutes (almost 3 hours) before any PCI survival benefit is lost. Patient presentations with the “maximal allowable” time to catheter placement across the lesion are as follows:

- For patients presenting within 2 hours of symptom onset—94 min
- For patients presenting beyond 2 hours of symptom onset—190 min
- For patients less than 65 years old—71 min
- For patients greater than 65 years old—155 min
- Anterior STEMI—115 min
- Nonanterior STEMI—112 min

Further analysis combined commonly encountered clinical variables in typical STEMI presentations:

- Patient presentation within 2 hours of symptom onset and ...
  - Anterior STEMI with age less than 65 years—40 min
  - Anterior STEMI with age greater than 65 years—107 min
  - Nonanterior STEMI with age less than 65 years—58 min
  - Nonanterior STEMI with age greater than 65 years—168 min
- Patient presentation beyond 2 hours of symptom onset and ...
  - Anterior STEMI with age less than 65 years—43 min
  - Anterior STEMI with age greater than 65 years—148 min
  - Nonanterior STEMI with age less than 65 years—103 min
  - Nonanterior STEMI with age greater than 65 years—179 min

The importance of symptom duration as well as patient age and infarct location affects reperfusion therapy decisions.
Patients who are not able to rapidly reach the PCI suite should be considered for fibrinolysis. This analysis does not represent the standard for treatment comparisons. Delays to reperfusion therapy are not without negative consequences, as noted in a subset of patients in the GRACE database. The investigators examined the outcome impact of treatment delays on STEMI patients receiving reperfusion therapy. This study involved 3959 patients from 106 hospitals in 14 countries who presented within 6 hours of chest pain onset and underwent either PCI (55%) or fibrinolysis (45%). Delays in reperfusion were associated with increased mortality for both treatment strategies and were more pronounced in those patients receiving fibrinolysis. A cooperative effort between all providers and units can reduce markedly the door-to-therapy time in STEMI patients. A “STEMI alert” system, analogous to the “trauma alert” approach, mobilizes hospital-based resources, optimizing the approach to the AMI patient. This system, whether activated by data gathered in the ED or in the field, has the potential to offer time-sensitive therapies in a rapid fashion. In fact, emergency physician activation of the catheterization laboratory demonstrates very high rates of accurate STEMI diagnosis while markedly reducing the time to definitive therapy with very low rates of false activation (i.e., the STEMI mimicker). The ACC/AHA recognizes the numerous challenges and potential difficulties in achieving these reperfusion therapy time goals.

Reperfusion Therapy in Cardiogenic Shock

Patients with AMI who present with cardiogenic shock, which occurs in up to 10% of cases, demand special consideration because of a mortality rate approaching 80%. Fibrinolysis is not effective in these patients, with a significantly lower coronary perfusion pressure. In shock, the occlusive thrombus is not exposed to the fibrinolytic agent, resulting in clinical failure of the drug. In large fibrinolytic trials such as GISSI-1 and ISIS-2, AMI patients presenting in cardiogenic shock do not benefit from fibrinolysis. Conversely, primary PCI has been investigated in more than 600 patients in several small studies. A cumulative analysis revealed a significantly lower mortality rate (45%) compared with placebo or historical controls. The SHould we emergently revascularize Occluded Coronaries in cardiogenic shock? (SHOCK) trial compared the outcomes of AMI patients presenting in cardiogenic shock. Patients were randomly assigned to emergency revascularization (PCI or emergent CABG) or initial medical stabilization, including fibrinolysis. The primary endpoint was mortality from all causes at 30 days; 6-month survival was the secondary endpoint. Overall mortality at 30 days did not differ significantly between the revascularization and medical therapy groups. Six-month mortality was lower in the revascularization group than in the medical therapy group. The investigators conclude that in AMI patients with cardiogenic shock, emergency revascularization does not significantly reduce overall mortality at 30 days. After 6 months, however, there is a significant survival benefit. Thus, when catheterization facilities are not available, fibrinolytic therapy should be given to eligible patients, and urgent transfer to an interventional facility should be strongly considered.

Resuscitated Cardiac Arrest with STEMI

The management of the STEMI patient resuscitated from cardiac arrest includes strict blood pressure and serum glucose control as well as the consideration of therapeutic hypothermia. Specific STEMI issues to consider include not only the type of reperfusion therapy offered but also the extent and timing of such treatment. In a series of 186 patients who underwent immediate PCI after successful resuscitation for cardiac arrest complicating STEMI, PCI was successful in almost 90%, restoring adequate coronary perfusion. Interestingly, 54% survived beyond 6 months with a large proportion with intact neurologic function. A second investigation reviewed 135 patients with resuscitated cardiac arrest complicated by STEMI. Among those patients who were conscious at the time of PCI, invasive therapy restored coronary perfusion in 96% of cases, and all of these patients survived without neurologic deficit. The outcome in the comatose patient subgroup was less favorable, with approximately a 50% survival rate demonstrating good neurologic outcome.

Another study compared reperfusion strategies in cardiac arrest survivors who experienced STEMI in the immediate postresuscitation period. Regardless of the reperfusion method, approximately 65% of patients survived to 6 months, with 53% demonstrating good neurologic function. The rate of an adverse event such as significant hemorrhage in those patients who received greater than 10 minutes of CPR was similar in those patients who did and did not receive a fibrinolytic agent.

Therapeutic hypothermia, when combined with PCI, in resuscitated cardiac arrest STEMI patients demonstrates an impressive rate of survival with good neurologic outcome. In a series of 40 such patients, therapeutic hypothermia coupled with PCI demonstrated a significantly improved survival. These retrospective case series suggest that aggressive reperfusion therapy may contribute to a favorable survival rate in the resuscitated cardiac arrest STEMI patient with either fibrinolytic or PCI reperfusion therapy.

Transfer of a Patient with Acute Coronary Syndrome

There are several indications for the transfer of a patient with ACS to a facility with PCI capability. These include rapid access to PCI (catheter across the lesion within 90 minutes of arrival to the initial hospital), persistent hemodynamic instability or ventricular dysrhythmias, and postinfarction or postperfusion ischemia. Hospital transfer for PCI is also suggested in patients with fibrinolytic contraindications who may benefit from PCI or CABG.

The urgent transfer of a fibrinolytic-eligible STEMI patient for PCI to another institution is not recommended until fibrinolytic therapy is initiated if a delay in PCI application is anticipated. In fact, the ACC/AHA notes “in hospitals without PCI capability, immediate transfer for primary PCI is a treatment option when the expected door-to-balloon time is within 90 minutes of first medical contact.” If delays in PCI performance are anticipated and the patient is an acceptable candidate for fibrinolysis, the fibrinolytic should be started before or during transport to the receiving hospital.

Many institutions are not PCI capable. Thus, the decision for the emergency physician involves not only the relatively simple “lytic vs. PCI” issue but also the potential need for urgent transfer to a larger center. The Primary Angioplasty in patients transferred from General Community hospitals to specialized PTCA Units with or without Emergency thrombolysis (PRAGUE) investigators explored the potential benefit of PCI over fibrinolysis and the all-important impact of transfer in the STEMI patient presenting to a noninterventional hospital over a multiyear follow-up study. At the end of the 5-year period, the cumulative incidence of composite endpoint (death from any cause, recurrent infarction, stroke, and/or revascularization) was 53% in fibrinolytic patients compared with 40%
in the PCI group. The investigators concluded that the early benefit from a transfer-related invasive strategy is sustained over the 5-year follow-up period. The benefit is obtained largely due to a lower event rate in the first 30 days following presentation.\(^{208}\)

The potential need to transfer the STEMI patient over long distances can also impact reperfusion therapy decisions. In a study of patients presenting to rural hospitals in central Illinois, a standard treatment protocol initiated by the emergency physician included rapid hospital transfer for PCI. Fibrinolysis was used at the discretion of the treating emergency physician when either unanticipated delays occurred or the physician felt such therapy was necessary. In this study, the median initial hospital arrival to transfer initiation time was 46 minutes; a large portion of this delay was due to the transport vehicle. The transferring and accepting hospital arrival to catheter median placement times were 29 minutes and 35 minutes, respectively. Overall, the initial hospital arrival to catheter placement times was 117 minutes. No transfer-related complications occurred. Sixty percent of STEMI patients received some form of reperfusion therapy in this rural system within 120 minutes.\(^{209}\) This prolonged transport issue is also explored in an established treatment system involving 30 hospitals ranging up to 210 miles from the PCI center. Over a 2.5-year period, 1345 consecutive STEMI patients were managed, including 1048 patients transferred from non-PCI hospitals.\(^{210}\) These two investigations suggest that rapid transfer for PCI in the STEMI patient can occur in the rural setting with acceptable time to therapy.

### Potential Pharmacologic Management Approach

The patient with stable chest pain who presents with a normal to minimally abnormal ECG and a negative serum marker is best managed initially with NTG sublingually or topically in combination with aspirin. Resolution of the discomfort with continued stability probably does not warrant further ED pharmacologic management. Continued or recurrent pain in the ED may be treated with parenteral morphine sulfate. Continued pain may ultimately require intravenous NTG and heparinization with unfractionated or LMW heparin with additional antiplatelet therapy using either clopidogrel or GPI. The patient with “stable” UA (i.e., new-onset or altered pattern but now symptom free and lacking abnormal serum markers and ECG) does not require heparin or other more aggressive platelet inhibition therapy in most cases.

The ACS patient with an abnormal ECG, particularly ST segment and T wave abnormalities, or elevated serum markers may warrant numerous therapies, including ASA, heparin, and other antiplatelet agents. NTG may be administered by the topical or intravenous route. The patient with recurrent angina may also benefit from such an approach. Heparin therapy is generally indicated in this instance.

The AMI patient without ST segment elevation requires aspirin, NTG, heparin, and morphine sulfate. Depending on hospital protocols and the type of ACS, clopidogrel can be administered in the ED or in the coronary care area. The patient with ST segment elevation AMI is treated with the preceding medications as well as considered for urgent revascularization, achieved by either fibrinolytic agents, PCI, or, in the rare case, CABG. Patients who are to undergo acute PCI should receive GPI therapy, either in the ED or in the catheterization laboratory, depending on the local protocol.

### KEY CONCEPTS

- Anginal equivalent symptoms that are not characteristically associated with ACS vary widely and often distract from the diagnosis. Consider the age, diabetes, ethnicity, and gender with an atypical history.
- Limitations of the 12-lead ECG in ACS include initial nondiagnostic findings, evolving fluctuations with ongoing symptoms, anatomic myocardial “blind spots,” and confounding or obscuring patterns, such as LBBB.
- Biochemical markers for ischemia and infarction have a pivotal role for diagnosis, risk stratification, and treatment of ACS. Serial testing strategies substantially improve sensitivity when indicated.
- Functional testing strategies for ACS include graded exercise testing, echocardiography, myocardial scintigraphy, and coronary CT. Graded exercise testing with or without nuclear scintigraphy can be used in the patient with low to moderate suspicion for CAD who is able to exercise. Myocardial scintigraphy with pharmacologic stress can be used in the debilitated or older patient (i.e., unable to exercise). Echocardiography with pharmacologic stress is appropriate for the woman over age 45 years, the patient with diabetes mellitus, and in those patients with other forms of organic heart disease (valvular dysfunction and low cardiac output states). Coronary CT is still a new testing modality; its use is most appropriate in the younger patient yet its widespread application cannot be advised in that little data exist to appropriately guide its use.
- Advancements in other noninvasive imaging to assess ACS include coronary CTA and “triple rule-out” MDCT protocols; their role in the ED remains undefined.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
The term *dysrhythmia* denotes any abnormality in cardiac rhythm. In this chapter, we review dysrhythmias outside of cardiac arrest and those secondary to toxidromes. The physiology of normal and abnormal cardiac impulse formation and conduction is summarized, and diagnostic tools including the history, physical examination, and surface electrocardiogram (ECG) are discussed. With each rhythm disturbance, treatment options are identified for care prior to and in the emergency department (ED).

## CARDIAC CELLULAR ELECTROPHYSIOLOGY

The function of individual cells in the conductive and contractile tissues of the heart depends on an intact resting membrane potential. Na\(^+\), K\(^+\), and Ca\(^{2+}\) ions create the membrane potential and regulate conduction, hence contraction. The membrane potential is the result of a differential concentration of Na\(^+\) and K\(^+\) on each side of the cell membrane. The potential measures approximately 90 mV in normal resting nonpacemaker cells, with a relative net negative charge in the intracellular area (Fig. 77-1). This electrical gradient exists mainly due to the sodium-potassium exchange pump and the natural concentration-dependent flow of K\(^+\) out of the cell. A Na\(^+\)-Ca\(^{2+}\) exchange also exists, regulating the intracellular concentration of Ca\(^{2+}\), although this latter exchange contributes more to myofibril contraction than conduction.

Adenosine triphosphate (ATP) fuels Na\(^+\) transport out to the extracellular fluid, with Mg\(^{2+}\) used as a cofactor (see Fig. 77-1). This process creates an osmotic gradient, allowing Ca\(^{2+}\) to be exchanged for Na\(^+\) without energy expenditure. Disturbances in intracellular and extracellular ion concentrations from ischemia, electrolyte abnormalities, metabolic derangements, or drugs can alter the membrane potential and disrupt normal impulse generation, conduction, and myofibril contraction.

The remaining 90 mV of the resting membrane potential is generated from the flow of K\(^+\) down a concentration gradient toward the extracellular fluid (see Fig. 77-1). The cell membrane is far more permeable to potassium than sodium ions, resulting in a greater loss of intracellular positive charge. Abnormalities in the K\(^+\) gradient, as in extracellular hyperkalemia, can interfere with normal impulse formation and conduction.

In normal nonpacemaker cells, the application of an electrical stimulus causes the membrane potential to become less negative, termed depolarization. When the membrane potential reaches −70 mV, specialized channels open for Na\(^+\) entry, causing a rapid influx of positive charge into the cell. This “fast” channel activity further decreases the membrane potential and is augmented at approximately −30 to −40 mV by a second “slow” channel that allows Ca\(^{2+}\) influx. When channels close, the resting potential is restored by the sodium-potassium pump and the K\(^+\) concentration gradient, an event known as repolarization. This cycle can be traced with a cell microelectrode and is called the *action potential* (Fig. 77-2).

The microelectrode identifies the phases of cell energy change. Phase 4 represents electrical diastole, with the normal cell membrane at a resting potential of −90 mV. Nonpacemaker cells maintain this potential until an electrical stimulus arrives. When a stimulus arrives, abrupt membrane depolarization occurs (phase 0). Phase 1 is a short period of membrane repolarization, caused by the closure of the fast Na\(^+\) channels and transient K\(^+\) efflux from the cell. Phase 2 is the plateau phase of the action potential, in which the slow Ca\(^{2+}\) channels remain open, maintaining a near balance between ion influx and efflux. During this phase, an increase in the cytosol Ca\(^{2+}\) concentration occurs as both the extracellular and intracellular (within the sarcoplasmic reticulum) stores are mobilized. This increase in intracellular Ca\(^{2+}\) concentration facilitates mechanical coupling and myofibril contraction. Phase 3 represents the rapid membrane repolarization period as the slow channels close and K\(^+\) flows down the concentration gradient. The ATP-driven pump exchanges Na\(^+\) and K\(^+\) until the phase 4 resting potential is reached.

In nonpacemaker cells, additional depolarization from a second electrical stimulus is not possible when the membrane potential is more positive than −60 mV (initially achieved during phase 0 and maintained until phase 3), irrespective of impulse strength. This period is termed the *effective refractory period* (Fig. 77-3). At a membrane potential of −60 to −70 mV, a strong impulse can cause a response that is likely to be propagated, although abnormally; this response represents the *relative refractory period* (see Fig. 77-3). At a membrane potential of −70 mV or less, virtually all fast channels are ready for activity if properly stimulated.

Pacemaker cells differ from non-impulse-generating cells in two ways: their resting membrane potential is less negative, and they can spontaneously depolarize via slow Na\(^+\) influx during phase 4 (see Fig. 77-2). Pacemaker cells exist normally within the sinoatrial (SA) and atrioventricular (AV) nodes, with others found on the atrial surfaces of the AV valves and within the His-Purkinje system. Nonpacemaker cells may develop...
Figure 77-1. Flow of various ions across the myocardial cell membrane. Na⁺-K⁺ pump exchanges three Na⁺ ions for each two K⁺ ions, generating a net negative flow of 10 mV. The flow of K⁺ down the concentration gradient (dark arrow) generates another 80 mV of current. The Na⁺-Ca²⁺ exchange adds little to the resting potential. ATPase, adenosine triphosphatase. (From Marriott HJL, Conover MB: Advanced Concepts in Arrhythmias, 2nd ed. St. Louis, Mosby, 1989.)

altered resting potentials and undergo spontaneous depolarization under pathologic conditions, especially during ischemia.

After-depolarizations are fluctuations in membrane potential that occur as the resting potential is approached. These fluctuations may precipitate another depolarization (Fig. 77-4). After-depolarizations can occur just before full resting potential (early after-depolarizations) or after full resting potential (delayed after-depolarizations) is reached. Delayed after-depolarizations can arise from ischemia, pump failure, catecholamine excess, or electrolyte disturbances (especially K⁺, Mg²⁺, and Ca²⁺) and are enhanced by faster heart rates. Early after-depolarizations are associated with high resting membrane potentials and are more likely with slower heart rates.

ANATOMY AND CONDUCTION

The SA node is located at the junction of the right atrium and the superior vena cava. It is supplied by the right coronary artery (RCA) in 55% and the left circumflex artery (LCA) in 45% of patients. The normal SA node produces spontaneous depolarizations at a faster rate than other pacemakers and functions as the dominant pacemaker. When the SA node is injured or when other pacemakers generate impulses at a faster rate, nonsinus cardiac rhythms are observed. The SA node is normally under a slight parasympathetic dominance, which maintains the resting heart rate between 60 and 90 beats per minute in most adults. Patients whose parasympathetic tone is lost—after heart transplantation or with certain drugs—may have slightly higher resting heart rates. Hypothermia and increased relative vagal stimulation slow the rate of SA node impulse formation, whereas hyperthermia and increased relative sympathetic stimulation can increase the rate. Other pacemaker sites may be similarly affected by temperature and autonomic tone.

Figure 77-5 correlates the normal surface ECG events with those occurring at the electrophysiologic level. The impulse generated from within the SA node, imperceptible on the surface ECG, is propagated through the atrial tissue to the AV node. The atrial depolarization wave is characterized by the P wave on the surface ECG. The AV node is supplied by a branch of the RCA in 90% (termed right-dominant circulation) and by the LCA in the remaining 10% of patients (left-dominant circulation). Transport of the impulse within the AV node is slower than other areas of the conducting system (Table 77-1) because of the dependence on slow-channel ion influx to depolarize the cell membranes. This delay limits the ventricular rate and allows complete atrial emptying, providing a greater ventricular diastolic volume and increased stroke volume.

The two functionally distinct pathways within the AV node are termed alpha and beta. The alpha pathway has relatively
slow conduction and a short refractory period, and the beta pathway exhibits faster conduction and a longer refractory period. These paths are important in sustaining a reentrant tachycardia. The PR interval (normally 0.10–0.20 second) represents the time needed for conduction of a sinus impulse through the atria and AV node. Impulses originating in the low atrial tissues, the AV junction, or other infranodal tissues are associated with a shortened PR interval, along with impulses conducted to the ventricles by accessory pathways. PR prolongation usually results from nodal or supranodal conduction system disease.

After entry into the AV node, the impulse propagates down through the His bundle to the three main bundle branch fascicles. The His bundle is the most distal portion of the AV node and derives its blood supply from the RCA and left anterior descending (LAD) artery. The bundle branch fascicles beyond the His area supply the right bundle branch (RBB), left anterior-superior bundle (LASB), and left posterior-inferior bundle (LPIB) ventricular myocardium. Before separating into the three fascicles, His bundle fibers assume a topographic distribution. Thus, the appearance of a specific bundle branch pattern on the ECG can be the result of injury within a specific bundle branch or fascicle. The RBB and LASB are supplied by the LAD artery, and the LPIB can be supplied by either the RCA or the LCA. Occlusion of these vessels can cause a variety of conduction abnormalities. Commonly, RCA occlusion causes AV node block, whereas LAD artery occlusion usually causes infranodal (bundle branch) block.

After conduction down the three main bundle branches, each impulse is delivered to the Purkinje fibers. These Purkinje fibers propagate the impulse to the ventricular myocardium in a rapid and orderly fashion, allowing coordinated contraction and ejection of the ventricular contents. The QRS complex on the ECG is normally 0.09 second or less and represents ventricular depolarization; the T wave reflects repolarization. The total time of ventricular depolarization and repolarization is represented by the QT interval. The normal duration of the QT interval must be corrected for age, sex, and heart rate but is usually less than half of the R-R interval (between two surface beats).

The time required for complete conduction system repolarization is a function of the preceding cardiac cycle length. Shorter cycle lengths, represented as shorter preceding R-R intervals (i.e., faster heart rates), beget a shorter repolarization time. Conversely, longer cardiac cycles (slower heart rates) are associated with longer repolarization times. If an underlying slow sinus rhythm is present and an ectopic atrial impulse arrives between sinus impulses, the ectopic impulse may be conducted aberrantly (if bundles are relatively refractory), or it may be blocked (if the bundles are completely refractory). The preceding cycle is called the setup cycle because it dictates the refractory time of the infranodal conducting tissues.

The Ashman phenomenon refers to aberrant ventricular conduction of an atrial extrasystole after a long setup cycle, occurring in any irregular atrial dysrhythmia. Classically, the Ashman phenomenon is seen in atrial fibrillation, in which long-short cycle sequences are common. In normal subjects the RBB is the last part of the infranodal system to repolarize completely. Thus, aberrantly conducted impulses in the Ashman phenomenon usually assume a right bundle branch block (RBBB) appearance on the ECG.

Normally, the AV node is the preferred path for impulse delivery to the infranodal conducting system. In some patients, pathologic accessory pathways connecting atrial, infranodal conducting, and ventricular myocardial cells exist. These accessory pathways do not share the normal conduction delay of the AV node and may allow a rapid ventricular response rate and subsequent reduced cardiac output when supplanting the normal conduction system. Preexcitation refers to the early depolarization of ventricular myocardium when accessory paths are employed instead of the normal conduction system.

The AV node may serve as a subsidiary pacemaker in the absence of normal SA node activity; this node has an intrinsic impulse formation rate of 45 to 60 beats per minute. Infranodal pacemakers, found within the His bundle, the Purkinje system, and the bundle branches, usually function at a rate of 30 to 45 beats per minute. These rates may vary widely based on the underlying pathologic process present. In addition, as a result of ischemia or drug effect, atrial and ventricular nonpacemaker myocardial cells may become pacemakers.

**MECHANISMS FOR DYSRHYTHMIA FORMATION**

The three common causes of dysrhythmia formation are based on the electrophysiologic cause: altered automaticity, reentry, and triggered mechanisms. The history and ECG help distinguish between these mechanisms.

Altered automaticity can result from spontaneous phase 4 depolarization in nonpacemaker cells (abnormal automaticity) or an increase in the slope of depolarization in cells that normally undergo phase 4 depolarization (enhanced automaticity) (Fig. 77-6). Both types of altered automaticity occur in the setting of ischemia, electrolyte disturbances, and drug therapy.

Dysrhythmias caused by altered automaticity usually require a “warm-up” period. Clinically, a patient may report a gradual increase in palpitations versus an abrupt onset. A similar gradual increase in abnormal impulses on the ECG should accompany these symptoms. These dysrhythmias also tend to terminate gradually. Ventricular tachycardia within the first 24 hours after myocardial infarction is often the result of abnormal automaticity.

Enhanced automaticity occurs when catecholamine excess stimulates a non-SA nodal pacemaker source to become the dominant pacemaker. A typical enhanced automatic dysrhythmia is an idioventricular rhythm after myocardial infarction. Another enhanced automatic dysrhythmia is atrial or jun-
tional tachycardia with digitalis toxicity. In this setting, digitalis interferes with SA node impulse conduction and increases phase 4 depolarization in other myocardial cells, resulting in this dysrhythmia.

Reentry mechanisms are a common cause of narrow-complex (QRS duration less than 0.10 second) tachydysrhythmias, accounting for 50 to 80% of these rhythms. Reentry dysrhythmias are the result of abnormal conduction, as opposed to the abnormal impulse formation that occurs with altered automaticity dysrhythmias (Fig. 77-7). For reentry to occur, three conditions must exist: two paths (or a circuit) must be available, they must have unequal responsiveness, and one path must be slower.

In a reentrant dysrhythmia, an impulse reaching a circuit finds one of the two limbs refractory. The impulse is conducted down the nonrefractory limb to the distal tissues. If the initial refractory limb recovers during the time required for the impulse to traverse the other limb, however, the impulse can then enter the distal end of the latter limb and travel in a retrograde direction. The unequal responsiveness of the limbs creates a functional unidirectional block of one. When the impulse exits the second (retrograde conducting) limb, it may then reenter the first limb. Each cycle can be repeated, creating a self-sustaining, or “circus movement,” tachycardia. These cycles can be ordered or disordered (i.e., fibrillatory) and are termed microreentry when larger circuits are employed. In the AV node the alpha pathway usually serves as the anterograde limb and the beta pathway as the retrograde limb during a junctional reentrant tachycardia, although the converse can be seen in 10% of cases.

Reentry mechanisms are responsible for most regular narrow-complex tachycardias, some atrial and ventricular bigeminal and trigeminal rhythms, and many ventricular tachycardias. Clinically, these dysrhythmias start and terminate abruptly, without a warm-up period. Treatment is based on altering the refactoriness of the involved circuit by slowing or speeding conduction in one limb.

Triggered dysrhythmias are the result of after-depolarizations and are highly dependent on heart rate for propagation. Triggered dysrhythmias secondary to delayed after-depolarizations are associated with an intracellular Ca^2+ overload and can occur during reperfusion therapy in myocardial infarction and with digitalis toxicity. Ectopic atrial and junctional rhythms are often the result of this mechanism, along with some forms of ventricular tachycardia and bigeminy. These dysrhythmias are enhanced by faster heart rates and are inhibited by drugs that slow the heart rate or interfere with calcium entry into the cell.

In contrast, triggered dysrhythmias from early after-depolarizations are enhanced by slower heart rates. The classic dysrhythmia associated with this mechanism is a specific form of acquired polymorphic ventricular tachycardia termed torsades de pointes. Increasing the heart rate by overdrive pacing or drug administration (especially beta-adrenergic agonists) can terminate triggered dysrhythmias from early after-depolarizations.

### Classification of Drugs for Dysrhythmia Treatment

On the basis of their effect on the action potential and on impulse conduction in myocardial tissue, the drugs used to treat dysrhythmias can be classified into four major categories (Box 77-1).

Class I agents are further subdivided into three categories (A to C). Some agents exhibit properties of more than one class; for simplicity, these agents are grouped according to their major effect. Other agents fall outside this classification system and are discussed separately.

Class I agents exert their major effects on the fast Na^+ channels, resulting in slowed conduction and membrane stabilization. The subclasses are based on specific effects on action potential duration and conduction. Class IA agents moderately slow depolarization, prolong repolarization and action potential duration, and slow conduction. Class IB agents cause minimal slowing of depolarization and conduction and shorten repolarization and action potential duration. Class IC agents markedly slow depolarization and conduction and prolong repolarization and action potential duration.

Class II agents are the beta-adrenergic antagonists (blockers); these agents slow the SA node rate and AV node conduction. Beta-blockers also prolong the action potential and can depress conduction in ischemic myocardial tissues, although the normal His-Purkinje system is unaffected.

Class III agents prolong the action potential and refractory period duration, thus exhibiting a clinical antifibrillatory effect.

Class IV agents are the slow Ca^2+ channel entry antagonists, causing a depression of anterograde conduction through the AV node and suppression of other calcium-dependent dysrhythmias. Miscellaneous agents important in the emergency treatment of dysrhythmias include magnesium sulfate, digitalis, and adenosine.

Although all class I to IV drugs are used as antidysrhythmics, they are also associated with “prodysrhythmic” effects. The term refers to the exacerbation or the provocation of a dysrhythmia after institution of drug therapy. Prodysrhythmia occurs most often in those with existing structural heart disease receiving new or high doses of inciting agents, although it can occur with any use of these drugs. The class I and III agents cause prodysrhythmic effects in up to 15% of patients, including ventricular tachycardia. In general, the class IB agents are associated with the least (<2% incidence) and the class IC agents the most frequent (5-15% incidence) prodysrhythmic effects. One investigational class IC agent, vernakalant, has atrial specific activity, offering potential advantages in treating atrial dysrhythmias and limiting ventricular prodysrhythmia.

For the classes II and IV agents, the prodysrhythmic effects are an extension of the electrophysiologic actions manifested as bradycardia and increasing AV nodal block.

### Class IA Agents

All class IA agents slow conduction through the atria, AV node, and His-Purkinje system directly and decrease conduction in accessory pathways. Class IA agents also exhibit anticholinergic and negative inotropic effects, with disopyramide displaying the most prominent and procainamide the least effect on contractility. Both procainamide and quinidine have periph-
**Class I**
Sodium (fast) channel blockers. Slow depolarization with varying effects on repolarization. These "membrane-stabilizing" drugs have prominent antiectopic effects.

**Class IA**
Moderate slowing of depolarization and conduction. Prolong repolarization and action potential duration.
- Quinidine
- Procainamide
- Disopyramide

**Class IB**
Minimally slow depolarization and conduction. Shorten repolarization and action potential duration.
- Lidocaine
- Phenytin
- Tocainide
- Mexiletine
- Moricizine*
- Aprindine

**Class IC**
Markedly slow depolarization and conduction. Prolong repolarization and action potential duration.
- Flecainide
- Encainide
- Lorcainide
- Propafenone*
- Vernakalant (atrial specific/investigational)

eral vasodilatory actions as a result of alpha-adrenergic blockade, which contributes to hypotension after administration. Disopyramide has vasoconstrictor properties, which together with its marked negative inotropic effects limits its use for acute dysrhythmia treatment.

Each class IA agent has high oral bioavailability. This route may be useful in the emergency treatment of certain dysrhythmias when symptoms are minimal. All class IA agents, particularly quinidine and procainamide, prolong ventricular repolarization and lengthen the QT interval. These changes mirror an increased risk of acquired polymorphic ventricular tachycardia in some patients treated with these agents. The aggregate incidence of proarythmic effects appears to be approximately 5% with this class.

**Procainamide**
Procainamide is the most commonly used class IA agent in the emergency treatment of selected ventricular and supraventricular dysrhythmias. Intravenous procainamide at a rate of 20 to 30 mg/min is recommended until the dysrhythmia is terminated, hypotension occurs (defined as a drop in the mean blood pressure of 15% or greater of the pretreatment value, or to a systolic pressure below 90 mm Hg), the QRS complex widens (to >50% of the pretreatment width), or a total dose of 18 to 20 mg/kg is administered (12 mg/kg if congestive heart failure is present). For convenience, some clinicians routinely start with a loading dose of 1 g, though this arbitrary limit can impair the success of this agent.

As result of its anticholinergic properties, intravenous procainamide may cause a transient increase in heart rate when used to treat a supraventricular dysrhythmia. A decrease in heart rate from its direct effect on AV nodal conduction and depolarization may also occur and force the termination of its use because of bradycardia. If successful, intravenous maintenance therapy is at a rate of 1 to 4 mg/min, with the lower rate suggested for elderly, congestive heart failure, and renal failure patients.

Oral therapy can be started at 2 g daily in divided doses (depending on the preparation) and titrated to effects and serum levels of procainamide and N-acetylprocainamide (an active metabolite). In addition to prodysrhythmia, other complications include heart block, orthostasis, abnormal liver function tests, and a lupus-like autoimmune syndrome. All side effects improve when the drug is discontinued.

**Quinidine and Disopyramide**
Quinidine and disopyramide are rarely used in current practice. While available for emergent rhythm control, both are better suited for long-term oral therapy. Oral quinidine is well absorbed and is eliminated primarily by hepatic metabolism (50–80%), with some renal excretion. The initial daily oral dose for adults is 150 to 300 mg every 6 hours, with therapeutic serum levels of 3 to 8 µg/mL. Oral quinidine can also be used in the pharmacologic conversion of atrial fibrillation but requires extended (2–6 hours) observation (see Box 77-1). Quinidine may have a role in ventricular dysrhythmia prevention in Brugada's syndrome. Sustained-release preparations are best reserved for use after successful titration with short-acting preparations.
Intravenous disopyramide is not approved for use in the United States. Oral doses are well absorbed (80–95%) by the gastrointestinal tract and are eliminated by hepatic metabolism (50%) and renal excretion. Treatment begins with 400 to 800 mg/day in four divided doses, and the therapeutic serum level during long-term use is 2 to 4 µg/mL. Approximately 15 to 20% of patients treated with disopyramide develop new or increased clinical signs of congestive heart failure, limiting its long-term use.

Class IB Agents

Class IB agents slow conduction and depolarization the least of the class I agents, and they shorten repolarization and action potential duration instead of the prolongation seen with the classes IA and IC agents. These agents have little effect on accessory pathway conduction. The two class IB agents most commonly administered are phenytoin and lidocaine.

Lidocaine

Lidocaine is rapidly absorbed by the gastrointestinal tract but largely inactivated by first-pass hepatic metabolism, limiting oral utility. Lidocaine can suppress dysrhythmias secondary to enhanced automaticity, although it has little effect on abnormal automatic rhythms. When used for ventricular dysrhythmias, lidocaine successfully terminates 60 to 90%, depending on the specific rhythm encountered and the dose used. Lidocaine can also depress SA and AV node conduction and slow the ventricular rate, usually in the presence of myocardial ischemia. These pharmacologic properties may disproportionately limit its clinical popularity, despite the small risk, ease of use, and effectiveness. In atrial fibrillation or flutter, lidocaine may cause a transient increase in conduction and heart rate. Otherwise, it is usually devoid of effects on autonomic and vascular tone, myocardial contractility, and the surface ECG in therapeutic doses.

Phenytoin

Phenytoin is mostly used for the treatment of generalized seizures, but it can have a limited role in the emergency treatment of dysrhythmias. Phenytoin is 70 to 90% protein bound and is eliminated primarily by hepatic metabolism, with only 5% excreted by the kidneys. During long-term outpatient use, the daily dose often must be lowered as metabolism slows. Many drugs increase or decrease phenytoin levels through their effects on protein binding and metabolism.

Intravenous phenytoin should be infused at a rate no greater than 50 mg/min (25 mg/min in those with heart failure). In therapeutic doses, phenytoin has little effect on the ECG aside from mild shortening of the PR and QT intervals. Intravenous loading should be discontinued if the dysrhythmia is controlled, hypotension or conduction delays develop, or after a total dose of 18 mg/kg is administered. Although serum phenytoin levels between 10 and 20 µg/mL are therapeutic for seizure prophylaxis, lower serum levels may be adequate for rhythm controls. In terms of rhythm management, phenytoin is useful only in the setting of concomitant seizures and ventricular dysrhythmia.

Other Class IB Agents

Mexiletine and tocainide are not used in the ED and rarely employed elsewhere. A positive response to intravenous lidocaine predicts successful dysrhythmia control with either of these agents. Their side effects are similar to those seen with lidocaine, although the incidence of dizziness and paresthesia is slightly greater. Moricizine hydrochloride is a phenothiazine derivative that shares activity with classes IA, IB, and IC agents. Moricizine has no role in the initial management of ventricular dysrhythmias.

Class IC Agents

The class IC agents profoundly slow depolarization and conduction and have significant antidyssrhythmic properties. The true incidence of prodysrhythmic effects in this class is unclear because these agents are used primarily in patients refractory to more conventional therapies, creating a potential magnification of the effect. Up to 15% of patients treated with class IC agents experience new or increased ventricular dysrhythmias, with up to 5% developing polymorphic or sustained monomorphic ventricular tachycardia. The incidence of prodyssrhythmia, especially polymorphic ventricular tachycardia, increases when IC agents are used in high doses in those with decreased ejection fraction. The total morbidity and mortality associated with any cardiac-related event (including dysrhythmias and shock) is also relatively high when these agents are used in the long term, even in patients being treated for mildly symptomatic dysrhythmias.

Class IC agents are approved only for oral use in the United States and have a limited role in the initial management of dysrhythmias. In Europe, these agents are employed for emergent intravenous dysrhythmia treatment. Each agent can increase the PR, QRS, and QT intervals on the ECG, although this does not reliably predict the risk of polymorphic ventricular tachycardia.

Flecainide

Flecainide, in addition to the electrophysiologic effects shared with all class IC agents, increases the refractory period in most accessory pathways. It has a mild negative inotropic effect, with up to 4% of patients experiencing increased heart failure. Flecainide is well absorbed from the gastrointestinal tract, with 30% excreted unchanged in the urine and 70% metabolized by the liver. The mean although variable serum half-life is 14 hours.

Flecainide controls 60 to 90% of all ventricular dysrhythmias and between 40 and 100% of supraventricular dysrhythmias. Side effects may occur in up to 40% of patients but are usually minor, and respond to a decreased dosage. These include visual disturbances, dizziness, paresthesia, headache, and nausea. An increase in ventricular rate may occur in 10% and hypotension in another 10% of patients in addition to the previously mentioned risk of heart failure. Oral therapy requires ECG monitoring for both QRS and QT prolongation. Single-dose oral flecainide can terminate atrial fibrillation in outpatients.

Encainide

Encainide has an electrophysiologic profile similar to that of flecainide, with the advantage of a less negative inotropic effect. It is well absorbed from the gastrointestinal tract, with extensive hepatic metabolism forming two active metabolites. The serum half-life of all active forms is 3 to 12 hours. Treatment is usually begun with 75 mg/day in three doses and increased every 3 to 5 days on the basis of response and side effects to a maximal daily dose of 300 mg. It is not approved for intravenous use. The side effects and success rates are similar to those seen with flecainide.
Propafenone

This investigational class IC agent has atrial specific activity and converts approximately 50 to 60% of patients with new-onset nonvalvular atrial fibrillation in doses of 2 to 3 mg/kg.\textsuperscript{1,10} Vernakalant offers promise of effects similar to class IC agents in the target rhythms with less ventricular prodyhythmia.

Class II Agents

In general, class II agents (beta-blockers) are best suited to control ventricular response rates and break a reentrant circuit in a supraventricular dysrhythmia than to treat a ventricular dysrhythmia. In the setting of acute myocardial infarction, limiting ventricular dysrhythmia and reinfarction are important indications for beta-blockers, especially metoprolol.

All beta-blockers are active at both \( \beta_1 \) and \( \beta_2 \)-receptors (Table 77-2) but to varying degrees. Those with more prominent \( \beta_1 \) effects are termed cardiospecific. Through their effects on \( \beta_1 \)-receptors, all class II agents slow SA node impulse formation and depress myocardial contractility to varying degrees. \( \beta_1 \) selectivity is desirable because a lowered incidence of bronchospasm is observed with therapeutic antidysrhythmic doses. The usual effect of class II agents on the ECG is slowing of the heart rate and PR prolongation, with no effect on QRS and QT duration.

Relative contraindications for beta-blockers include asthma or chronic obstructive lung disease, advanced congestive heart failure, and third-trimester pregnancy. Beta-blockers should not be used in patients with bradycardia or greater than first-degree heart block. Although often used together during long-term oral therapy, intravenous beta-blockers should be given with great caution after recent intravenous calcium channel antagonist (class IV) use because of the increased risk of hemodynamic side effects. Acute side effects of beta-blockers include bronchospasm, heart failure, excessive bradycardia, hypotension, and vasospasm (especially with Raynaud’s syndrome).

Propranolol

Propafenone is nonselective and well absorbed by the gastrointestinal tract. It undergoes extensive first-pass liver metabolism after oral intake, requiring a much higher dose by this route than an equipotent intravenous dose. The serum half-life is 3 to 6 hours, requiring a four times daily dosing regimen. Therapy is usually monitored by rhythm control and side effects, not serum levels. Oral dosages begin at 80 mg/day of a short-acting preparation in divided doses. Oral propranolol is better suited for maintenance therapy than intravenous propranolol for acute dysrhythmia treatment.

Propranolol is effective in terminating 30 to 80% of reentrant supraventricular tachycardias (SVTs), depending on the pathway, especially if the rhythm is catecholamine induced. Because of its relatively long effect, it is not commonly employed in emergency settings. Its use in other rhythms is associated with a lower success rate and increased side effects when compared with class I agents.

Esmolol

Esmolol is an attractive beta-blocker in the emergency treatment of supraventricular tachydysrhythmias. It is \( \beta_1 \) selective with a rapid onset of action, with a 5- to 10-minute duration of effect. The brief clinical effect is the result of its short elimination half-life (9.5 minutes) because of metabolism by plasma cholinesterase. An intravenous bolus of 500 \( \mu \)g/kg esmolol is usually followed by a continuous infusion starting at 50 \( \mu \)g/kg/min. Discontinuance of the infusion results in a rapid decrease in therapeutic and toxic effects. If the dysrhythmia persists after the initial bolus and infusion, a repeated loading dose should be given and the infusion rate should be increased in increments of 50 \( \mu \)g/kg/min. Usually an esmolol infusion rate of 200 \( \mu \)g/kg/min or less is effective, and the maximal recommended rate is 300 \( \mu \)g/kg/min.

Metoprolol

Metoprolol is available in oral and intravenous preparations. Although not approved for initial dysrhythmia treatment in the United States, metoprolol (5–10 mg IV every 10–15 minutes titrated to response) will slow atrial and nodal fast rhythms and is often used for these purposes.

Nadolol and Acebutolol

Nadolol and acebutolol are used for oral dysrhythmia treatment but are not approved for intravenous use. The effectiveness and side effect profiles are similar to those of propranolol and metoprolol, aside from a lowered risk of bronchospasm with acebutolol, which has an intrinsic sympathomimetic effect.

Class III Agents

This class is called the antifibrillatory group for the treatment of atrial and ventricular fibrillation. All class III agents prolong the refractory period and action potential duration but have variable effects on the QT interval.\textsuperscript{11} In general, class III agents are alternative drugs to the class I agents for the treatment of many ventricular and atrial dysrhythmias.
Amiodarone was previously the most commonly used class III agent. Because of its profound hemodynamic effects and the emergence of newer class III drugs, it is no longer available in the United States.

Amiodarone

Amiodarone is approved for the treatment of both ventricular and supraventricular dysrhythmias, including atrial fibrillation or flutter and accessory pathway syndromes. In addition to features of all class III agents, amiodarone prolongs the action potential duration and refractory period, slows automaticity in pacemaker cells, and slows conduction in the AV node. It also displays a noncompetitive blockade of adrenergic receptors and causes smooth muscle relaxation. When given intravenously, amiodarone may cause a mild drop in blood pressure and heart rate along with a slight decrease in contractility. The recommended intravenous dose is 3 to 5 mg/kg over 10 to 15 minutes.

After an oral dose, absorption is slow and erratic, varying widely among subjects. The serum half-life is about 50 days during long-term oral use and approximately 25 hours after a single intravenous dose. Because of the unusual pharmacokinetics, oral dosing regimens vary widely, starting at 600 to 1000 mg/day initially for up to 7 days, followed by 400 to 800 mg/day for a maintenance dosage. The acute side effects of amiodarone are primarily limited to hypotension, bradycardia, and heart failure (Box 77-2).

Between 1 and 3% of patients experience prodrhythms with long-term amiodarone use, often without QT prolongation. Torsades de pointes is rare (<1% with long-term use and much less with acute use). Long-term amiodarone use is associated with significant side effects, including prominent extra-cardiac issues, forcing many patients to discontinue treatment. Amiodarone also causes an increase in the serum level of many agents, especially digoxin and warfarin. It can cause an additive risk of bradycardia and hypotension when used in conjunction with calcium channel and beta-adrenergic blockers. Long-term amiodarone use can cause pulmonary fibrosis, which can increase dyspnea. Also, amiodarone potentiates the rhabdomyolysis seen with simvastatin, a common cholesterol-lowering agent.

**Ibutilide**

This agent is approved in the United States only for intravenous use. When it is given in a dose of 0.015 to 0.02 mg/kg, approximately 50 to 65% of patients convert from atrial fibrillation or flutter to a sinus rhythm, usually within 20 minutes. Prolongation of the QT interval and prodrhythms, especially torsades, are more common than with amiodarone when used chronically (but similarly rare in acute use) with few other side effects. This drug is an alternative to intravenous procainamide for pharmacologic conversion of atrial fibrillation and flutter in the ED, with easier use and a good safety profile offset by higher cost.

**Sotalol and Other Agents**

Sotalol (a mixed class III–adrenergic blocking agent) has a limited ED role and is associated with a higher incidence of prodrhythms (especially polymorphic ventricular tachycardia) than other class III agents. It is used intravenously for conversion of atrial fibrillation but offers limited advantages over other regimens. Dofetilide, droperidone, and azimilide are investigational class III agents that possess other properties but have not clinically replaced the class I or III agents.

**Class IV Agents**

Class IV agents block the slow calcium channels in myocardial and vascular smooth muscle cells. Each agent exhibits activity at both the myocardial and peripheral vascular levels, with specificity for particular areas within the group. Verapamil and diltiazem exhibit the most potent effects on myocardial cell calcium entry, conduction, and contractility. Verapamil has the least effect on peripheral vascular tone, and diltiazem has an effect intermediary between that of verapamil and nifedipine. Both verapamil and diltiazem have a role in atrial and AV nodal tachycardias. Verapamil is often forgotten or shunned because of perceived relative side effect differences compared to diltiazem, yet both perform similarly well in practice. Nonetheless, diltiazem is the much more commonly used class IV agent currently.

Verapamil and diltiazem have little direct effect on accessory pathways, but since the native conduction system may participate in such a syndrome, these should be used only when anterograde conduction through the AV node exists (seen as narrow QRS complexes). Both slow conduction within the AV node (primarily at the atrial-His level) more than within the SA node. These actions are partially reversed by atropine. After an intravenous dose of either agent, the ECG is usually unchanged aside from a slower heart rate and prolonged PR interval. Intravenous class IV drugs should not be used in patients with second- or third-degree AV block and should be used with close monitoring in those with first-degree block.

Calcium chloride, 500 to 1000 mg (5–10 mL of a 10% solution), can reverse or prevent verapamil-induced hypotension. Calcium salts attenuate the peripheral vasodilatory

actions without altering the chronotropic (antidysrhythmic) effects of verapamil. For patients with borderline hypotension, administering 500 mg of calcium chloride prior to verapamil is an alternative approach. If verapamil-induced hypotension persists after calcium administration and intravenous fluids, use a direct-acting vasopressor. Aside from AV block, hypotension, and congestive heart failure, verapamil can cause other side effects, including nausea, vomiting, constipation, dizziness, nervousness, and pruritus.

**Diltiazem**

Oral doses are rapidly absorbed, although a significant first-pass effect is seen. Intravenous diltiazem (0.25 mg/kg over 2 minutes, followed by 0.35 mg/kg 15 minutes later if the first dose is unsuccessful) controls the ventricular response rate in 90% of patients with atrial fibrillation and atrial flutter and is associated with minimal hypotension. If the intravenous bolus is successful, a continuous infusion (5–15 mg/hr initially) or an oral dose (60–90 mg initially) may sustain the response.

**Verapamil**

Verapamil terminates or controls the ventricular response rate in 80 to 90% of tachycardic rhythms. Intravenous verapamil is given at a dosage of 0.1 mg/kg over 1 to 2 minutes; for the average healthy adult, this translates to a dose of 5 to 10 mg. In elderly patients or those with preexisting borderline hypotension (systolic blood pressure of 90–110 mm Hg), a smaller dose (0.05 mg/kg, or 2.5-mg increments) should be employed. Repeated doses (either the same or larger, up to twice the initial dose if there is no response in younger patients with cardiovascular stability aside from tachycardia) should be given every 10 minutes on the basis of response. Use of a longer dosing interval, especially if over 30 minutes, may interfere with successful treatment of a dysrhythmia because of redistribution.

Verapamil is rapidly absorbed from the gastrointestinal tract but undergoes extensive first-pass liver metabolism. The drug is 90% protein bound and is eliminated primarily by renal excretion. After an oral dose, the duration of effect is 4 to 6 hours, with a total elimination half-life of 3 to 12 hours. Daily maintenance with 120 to 720 mg of a short-acting preparation in four divided doses is recommended for prophylaxis from recurrent dysrhythmias. A long-acting preparation of verapamil is available but not approved for the treatment of dysrhythmias.

**Miscellaneous Agents**

**Digitalis**

Digoxin is the main form of digitalis used in the emergency treatment of cardiac dysrhythmias. In addition to their positive inotropic effects, digitalis compounds have variable effects on myocardial cells (Table 77-3). These electrophysiologic effects are both excitant and depressant. Digitalis excitant effects cause an increase in altered automatic and triggered ectopic impulses, particularly when it is given in toxic doses. Digitalis also depresses conduction and lengthens refractoriness in the AV node in therapeutic doses. Although the therapeutic effects are primarily the result of the depressive actions, toxic dysrhythmias may be the result of either or both of these mechanisms.

*Indirect autonomic effects (vagotonic and sympatholytic). D, decreases; I, increases; 0, minimal effect.

Digitalis controls the ventricular rate in narrow-complex tachycardias, including atrial fibrillation, atrial flutter, and paroxysmal supraventricular tachycardia (PSVT). Because of its slow onset of action and narrow therapeutic window, digitalis is not a first-line agent for emergency therapy. Digoxin is a complementary agent and useful in the outpatient management of these supraventricular rhythms, particularly when underlying heart failure is present.

Emergently, the first intravenous digoxin dose is commonly 0.5 mg in adults. A clinical effect may be seen within 30 minutes, but the peak effect does not occur until 11/2 to 2 hours. To optimize, repeat doses of 0.25 mg IV every 4 to 6 hours may be needed up to a total dose of 1.5 mg. The latter ceiling is arbitrary; some patients may require a higher dose to control rate but risk increased side effects.

Digoxin is excreted 50 to 75% unchanged in the urine and is 25% protein bound with a large volume of distribution. The serum half-life is 24 to 48 hours, allowing a daily or every other day maintenance regimen. Side effects of digoxin are listed in Box 77-3 and are enhanced by hypokalemia, hypercalcemia, hypomagnesemia, increased catecholamines, and severe acid-base disturbances. The concomitant use of quinidine can increase the serum levels of digoxin by interfering with renal and nonrenal elimination.

Two misconceptions about digoxin persist. Often it is used in atrial fibrillation because of a belief that conversion to a sinus rhythm is more likely than after the use of other rate-controlling agents, which is a fallacy. Furthermore, beta-adrenergic and calcium channel blockers are often better tolerated than digoxin in the absence of ventricular dysfunction. Another concern is the safety of cardioversion during digoxin therapy and the possible development of ventricular dysrhythmias. If no clinical or laboratory evidence of toxicity is present, cardioversion of atrial fibrillation or flutter is safe, with little added risk of precipitating ventricular dysrhythmias compared with patients not receiving digoxin.

Magnesium

Magnesium has been in use for over 50 years as an antidysrhythmic, controlling the ventricular response rate in a variety of narrow-complex tachycardias, including atrial fibrillation, multifocal atrial tachycardia, and reentrant SVT. Magnesium (2–4 g as a slow IV bolus) can also terminate ventricular tachycardia, including digoxin-induced and polymorphic ventricular tachycardia (especially torsades de pointes).24 Aside from a central role in the latter rhythm, magnesium is generally a second- or third-line agent.

Adenosine

Adenosine is a naturally occurring purine nucleoside used for the intravenous treatment of narrow-complex tachydysrhythmias.25,26 It causes a concentration-dependent slowing of AV conduction and a slowing of conduction in both anterograde and retrograde paths of a reentrant circuit. Adenosine shortens the action potential duration and is devoid of effects on atrial contractility. In extremely low doses, adenosine causes selective coronary vasodilation. As the dose is increased to the amount needed for a maximal antidysrhythmic effect, peripheral vasodilatation occurs.

After an intravenous dose, adenosine has an onset of action of 5 to 20 seconds with a duration of effect of 30 to 40 seconds. It is eliminated primarily by deamination in endothelial and blood cells, with a 10-second serum half-life. Aside from a decreasing heart rate and an increasing AV block, adenosine has little effect on the ECG. Except in rare cases of catecholamine-induced ventricular dysrhythmias, adenosine has little effect on infranodal conduction. This fact, coupled with clinical data, prompted some to use adenosine as a diagnostic agent in the wide-complex tachycardias.27,28 For most patients with ventricular tachycardia, adenosine will have no effect on rhythm or blood pressure due to the pharmacologic behavior of the drug, though a small number will experience dysrhythmia relief and, rarely, collapse.29,30

An initial dose of 6 mg as a rapid bolus for adults weighing 50 kg or greater is recommended with flush through a large peripheral vein. If no response is seen within 1 to 2 minutes, the dose is doubled (12 mg) and repeated. If no effect is seen after a third 12-mg dose, the rhythm should be reassessed and another agent employed. Pediatric doses are of 0.05 mg/kg initially with doubling at similar intervals up to a total dose of 0.25 mg/kg.26

Side effects coincide with the onset of clinical effects and occur in up to a third of patients but are usually minor. These include flushing, dyspnea, chest pressure, nausea, headache, dizziness, transient bradycardia or heart block, and hypotension (seen rarely, from the vasodilatory properties). All resolve rapidly without treatment, although many patients are intensely uncomfortable for a short period. Other rhythms rarely seen after adenosine use include atrial fibrillation and ventricular tachycardia. Aminophylline and the other methylxanthines, caffeine and theobromine, antagonize the effects of adenosine, and diprydiamole potentiates its effects. Digitalis, calcium channel blockers, and benzodiazepines can all augment the activity of adenosine.

In comparative studies of patients with narrow-complex tachydysrhythmias, adenosine has response rates equivalent to those of verapamil and diltiazem (85–90% overall, 60% with first dose) and few serious side effects. Because of its short duration of action, recurrence of the tachycardia occurs in many (~25%). Because of the short effect, adenosine is not a therapeutic agent for atrial fibrillation or flutter and nonreentrant rhythms, although it can help unmask these rhythms when not apparent on the initial ECG. Similarly, adenosine should not replace a careful search for a ventricular source or the rare but potentially lethal combination of atrial fibrillation with an accessory pathway. The use of any drug that depresses the AV node primarily in these settings (including adenosine, though given the short effect it is rare) can result in precipitous hemodynamic collapse.29,31 Finally, adenosine often fails because it is used for the wrong reason, especially unrecognized atrial fibrillation or ventricular tachycardia.

**APPROACH TO DYSRHYTHMIA RECOGNITION AND MANAGEMENT**

Dysrhythmias are classified according to their electrophysiologic origin, ECG appearance, and underlying ventricular rate. Although overlap exists, the following categorization is useful:

- Bradycardias, sinus and atrial rhythms, SA and AV block
- Extrasystoles and parasystoles
- Narrow-complex (QRS < 0.12 second) tachycardias
- Preexcitation and accessory pathway syndromes
- Wide-complex (QRS ≥ 0.12 second) tachycardias

The treatment of specific dysrhythmias is divided into two broad categories on the basis of clinical stability, which is a continuum. Unstable patients have evidence of end-organ hypoperfusion from the dysrhythmia. Bedside ED symptoms and signs of unstable rhythms are:

- Hypotension
- Chest pain suggestive of myocardial ischemia
- Dyspnea or pulmonary edema
- Altered sensorium (from agitation to coma)

The latter three are more specific because absolute blood pressure values may vary widely. For example, a patient with chronic hypertension who has a blood pressure of 110/60 mm Hg and crushing chest pain with a wide-complex tachycardia at a ventricular rate of 180 beats per minute is “more unstable” than a young woman with a similar rhythm and a blood pressure of 88/50 mm Hg without other symptoms. Patients with an unstable rhythm deserve rapid pharmacologic or electrical therapy after a focused assessment, whereas stable patients can
be treated after a more thorough evaluation to identify the exact cause. In general, rapid unstable dysrhythmias aside from sinus tachycardia require sedation and cardioversion, especially when more than one symptom or sign of instability is present. Slow unstable dysrhythmias require temporary pacing, although atropine can be used while preparing for pacing.

The Initial Assessment of Stable Patients

The approach to the patient with a stable dysrhythmia is to gather subjective and objective data concerning the underlying rhythm. The following steps are key:

- Directed history
- Physical examination
- 12-lead ECG and rhythm strip
- Diagnostic and therapeutic interventions

When caring for a stable patient with a dysrhythmia, these steps are often taken concurrently (e.g., history taking during the initial physical examination and combined ECG monitoring with certain physical examination techniques). In the presence of clear or potential instability, it is important to obtain and interpret the ECG while preparing for pacing (slow rate) or cardioversion (fast rate).

In stable patients, one should elicit the nature of any symptoms, including the timing and velocity (gradual or abrupt) of symptom onset. It is valuable to ask each patient specifically about prior or recent palpitations, dizziness, chest pain, dyspnea, or syncope. Known previous dysrhythmia, ischemic or structural heart disease, and current medications will help better assess the underlying rhythm. For example, a 22-year-old man treated with propranolol for “palpitations” who seeks treatment for abrupt onset of a regular tachycardia with a QRS duration of 0.12 second at a rate of 200 complexes per minute is more likely to have a reentrant SVT with aberrant conduction than ventricular tachycardia. Conversely, a 55-year-old man with a history of a previous myocardial infarction and taking daily amiodarone who presents with palpitations and chest pain and a similar wide-complex regular tachycardia is more likely to have ventricular tachycardia. Occasionally, the family history can be helpful. The combination of deafness with paroxysmal palpitations, syncope, and a family history of sudden death strongly suggests a specific form of torsades de pointes. Early sudden cardiac death in family members also heightens the suspicion for Brugada’s syndrome.

On physical examination, one must look for evidence of end-organ hypoperfusion or clues to the cause of the dysrhythmia. Alteration in cognitive function (from mild excitation to depressed consciousness), diaphoresis, or dusky skin are findings of hypoperfusion. Cannon waves in the neck and variation in the intensity of the first heart sound or arterial pulse suggest AV dissociation, a feature of ventricular rhythms. These are a challenge to detect in most ED patients. Close auscultation of the heart sounds may detect valvular disorders. Certain clinical toxidromes, such as organophosphate, anticholinergic, and cyclic antidepressant ingestion have prominent physical findings.

The most important ECG observations are listed in Box 77-4. Diagnosis using a single lead can be adequate, but multiple leads (especially a 12-lead ECG) best define the dysrhythmia accurately. Occasionally, an apparently narrow-complex rhythm is discovered to be a wide-complex rhythm when a different lead is examined, or evidence of AV dissociation is revealed when the rhythm strip does not demonstrate this finding. The paddles from a defibrillator and monitor unit can be helpful for short periods, because a modified chest lead from this application will optimize the appearance of the P wave and QRS complexes. Finally, since the most useful information about paroxysmal dysrhythmias occurs at the onset and termination of the rhythm, these tracings should be saved.

A long rhythm strip (up to a minute) may be needed to define a dysrhythmia. Other adjuncts to standard ECG monitoring include increasing the paper speed and the use of esophageal electrodes. Normally, a paper speed of 25 mm/sec is used; when it is increased to 50 to 100 mm/sec, the relationship of the P wave to the QRS complex may be better defined (Fig. 77-8). Esophageal leads can also help better define the P-QRS relationship but are not readily available in most settings (Fig. 77-9).

The use of maneuvers that alter autonomic tone can help uncover the cause of dysrhythmias and terminate selected rhythms. Carotid sinus massage and the Valsalva maneuver increase vagal (parasympathetic) tone. Vagal maneuvers transiently slow AV conduction, which may help terminate or uncover the primary rhythm disturbance on the ECG. The use of ice packs or cold-water head dunking (with care to avoid asphyxiation) has similar effects, especially in children, through the diving reflex. Carotid sinus massage is best avoided in elderly patients because of the risk of embolic phenomena. Auscultation of the neck for bruits should be performed before carotid sinus massage is attempted. Ocular or rectal massage and inflation of MAST trousers are not recommended.

The effectiveness of any maneuver alone or in various combinations compared with pharmacologic treatment is unclear. Generally, reentrant dysrhythmias abruptly terminate or continue with little change in rate, whereas atrial fibrillation and tachycardia slow temporarily. Vagal maneuvers usually fail to terminate supraventricular dysrhythmias but rarely cause deterioration. The failure of vagal efforts may be from poor technique (carotid massage should not be performed upright and should target carotid body, not the base of carotid artery) or a selection bias (those who will respond to vagal maneuvers often do so before arrival).

**Pseudodysrhythmias**

Occasionally, an artifact on the ECG produces an apparent dysrhythmia. Muscle contraction or movement (especially

shivering, loose leads, and stray external signals from other electrical equipment and monitoring devices can produce these artifacts, called pseudodysrhythmias (Fig. 77-10). These findings may often be mistaken for serious ventricular dysrhythmias, including ventricular fibrillation. Pseudodysrhythmias illustrate the need to avoid treating the ECG solely without incorporating bedside patient findings.

### SPECIFIC DYSRHYTHMIAS

#### Bradycardia, Sinoatrial and Atrioventricular Block

Bradycardia, defined as a ventricular rate of less than 60 beats per minute, can be normal in well-conditioned subjects or the result of two basic disturbances. Depression of the dominant pacemaker, usually the sinus node, causes bradycardia. Another cause is conduction system block, in which the normal sinus node impulses are incompletely carried to the AV node and ventricular tissues. In both situations, a subsidiary pacemaker may assume the dominant role, with ventricular rates of 30 to 60 beats per minute. The rhythms seen with subsidiary pacemakers during SA and AV nodal block are called escape rhythms because they provide a physiologic escape from no impulse generation (asystole).

The treatment of bradydysrhythmias is based on the underlying cause and symptoms. The two options are intravenous atropine (0.5–1 mg for adults) and temporary pacing, either transcutaneous or transvenous. Bradycardias require emergency treatment only when the ventricular rate is less than 50 beats per minute with hypoperfusion or if the rhythm carries a high risk of progression to complete block. A transcutaneous pacemaker should be readily available if observation is planned. Asymptomatic bradycardia requires no therapy.

#### Sinus Bradycardia

Sinus bradycardia appears on the ECG as a regular rhythm at a ventricular rate below 60 beats per minute and a normal consistent P wave morphology and PR interval duration (Fig. 77-11). This pattern may be found in healthy adults, during sleep and periods of fright. Other causes include hypothermia, excessive parasympathetic or diminished sympathetic stimulation (often from drug therapy, especially beta-adrenergic and calcium channel blockers), and carotid sinus hypersensitivity. The last is sometimes seen in men with bradycardia or syncope while wearing a tight shirt collar. Sinus bradycardia may be seen in the early stages of an acute inferior wall myocardial infarction, resulting from parasympathetic stimulation. Generally, sinus bradycardia is a benign dysrhythmia and requires no specific treatment aside from that required for any underlying condition such as hypothermia or acute myocardial ischemia.

#### Sinus and Atrial Dysrhythmias

Sinus dysrhythmia is seen at variable rates in the normal ranges. The ECG features are similar to those of sinus bradycardia, aside from the varying and normal ventricular rate (Fig. 77-12). Atrial dysrhythmias have ECG features similar
Figure 77-10. Pseudodysrhythmia. In this case, atrial flutter waves appear to be present but are recognized as an artifact when examining the patient and the right side of the electrocardiogram.

Figure 77-11. Sinus bradycardia.

Figure 77-12. Sinus dysrhythmia (note slight irregularity).
to those of sinus dysrhythmias, except that an atrial source other than the sinus node serves as the pacemaker, producing P′ waves that are consistent in structure yet different from the sinus P waves. The P′R interval may also vary from the normal sinus PR interval, which distinguishes these rhythms. Both dysrhythmias may be normal variants, with sinus dysrhythmias often resulting from respiratory variation. Neither has clinical significance except that they may be confused with other dysrhythmias. No treatment is required for these rhythms.

Sinoatrial Block and Escape Rhythms

The underlying feature of SA block is absent atrial depolarization, characterized by missing P waves. This lack of atrial depolarization occurs for three reasons: (1) failure of the sinus node to generate an impulse, (2) failure of impulse conduction out of the SA node, or (3) failure of the impulse to activate the atria, from either inability of the atria to depolarize or an inadequate stimulus intensity. SA block can be the result of ischemia, hyperkalemia, increased vagal tone, or drug therapy including beta-blockers, calcium channel blockers, and digitalis.

Incomplete SA block is diagnosed when an occasional P wave is dropped from the normal P-QRS-T sequence on the ECG. There are no P waves on the ECG (Fig. 77-13) in complete SA block (sinus arrest). Usually, a lower pacemaker emerges in complete SA block. If this pacemaker is within the AV node, the QRS complex is narrow and results in an “idiojunctional” escape rhythm at a rate of 45 to 60 beats per minute. Pacemakers within the His-Purkinje system usually result in a wide-complex “idioventricular” escape rhythm at a rate of 30 to 45 beats per minute.

The treatment of SA block is based on symptoms and includes atropine (except in the setting of digitalis toxicity) and temporary pacing. Patients without evidence of hypoperfusion should be observed without treatment. Class I antidysrhythmics should be avoided because they may extinguish an escape rhythm that is supporting life.

Sinus Node Dysfunction (Sick Sinus Syndrome)

This syndrome refers to a myriad of overlapping pathologic states ranging from frequent sinus pauses and bradycardia to the tachycardia-bradycardia syndrome. The latter represents bursts of an atrial tachydysrhythmia, usually atrial fibrillation, alternating with periods of sinus or atrial bradycardia. The tachycardia-bradycardia syndrome usually occurs in elderly persons but is also associated with ischemia, inflammatory diseases, cardiomyopathy, connective tissue diseases, and drug therapy (especially beta-blockers, calcium channel blockers, digitalis, and quinidine).

The diagnosis is made when symptoms, such as palpitations or syncope, are correlated with the bradycardia or tachycardia, usually through ambulatory ECG monitoring. The ECG manifestations vary, depending on the rhythm at presentation. Treatment consists of rate stimulation (with atropine or a pacemaker) or rate control (with calcium channel blockers, beta-blockers, or digitalis) when symptoms of hypoperfusion coexist. Either modality should be attempted with caution because excessive bradycardia or tachycardia may result, although generally the response is blunted (i.e., the heart rate increases to 90 beats/min or less after atropine). Recognition and referral are the mainstays of ED management. Long-term management is often a combination of an antidysrhythmic agent to suppress the tachycardia and a demand pacemaker (to provide a “floor” against excessive bradycardia).

Atrioventricular Block

AV block is the result of impaired conduction through the atria, AV node, or proximal His-Purkinje system. Although electrophysiologic studies using His bundle tracings can pinpoint the area of conduction disturbance, the surface ECG can provide information and guide clinical decisions. There are three common grades of AV block based on the ECG and clinical characteristics. First- and second-degree AV blocks represent an incomplete conduction disturbance, whereas third-degree block indicates complete AV conduction interruption.

First-Degree Atrioventricular Block. First-degree AV block is prolonged conduction of atrial impulses without the loss of any single impulse. This can occur at the level of the atria, AV node (most common), or His-Purkinje system (least common). On the ECG, a regular narrow-complex rhythm at mildly slow to normal ventricular rates with a prolonged PR interval (>0.20 second) is seen (Fig. 77-14). First-degree AV block is often a normal variant without clinical significance, occurring in 1.6% of healthy young adults. This type of AV block requires no specific treatment, though nodal depressing agents should be given with caution in this setting.

Second-Degree Atrioventricular Block. Second-degree AV block is an intermediate step between every impulse being conducted (albeit slowly) and no impulses being conducted. On the ECG this type of block is manifested as one or more sinus impulses failing to reach the ventricles. The conduction ratio in all types of incomplete AV block is described as the ratio of the number of P waves to the number of QRS complexes (e.g., 3:2, 4:3). Second-degree AV block can be divided into two types on the basis of the ECG appearance and clinical characteristics (Table 77-4).

*Primarily refers to conduction ratio.

AV, atrioventricular; ECG, electrocardiographic.
Figure 77-13. A, Incomplete sinus block. B, Complete sinus block (sinus arrest) with ventricular escape rhythm.

Figure 77-14. First-degree atrioventricular block.
Causes of Grouped Impulses

- Wenckebach mechanism (usually at atrioventricular node, but can occur elsewhere)
- Atrial tachycardia or flutter with alternating conduction (e.g., 2:1 with 3:2 or 4:1)
- Frequent extrasystoles (two or more impulses)
- Nonconducted atrial trigeminy
- Concealed or interpolated extrasystoles

**Type I Second-Degree Atrioventricular Block.** Type I second-degree AV block, also called Wenckebach or Mobitz I AV block, is associated with a conduction deficit within the AV node. On the surface ECG, a narrow-complex rhythm with the following three basic characteristics is seen (Fig. 77-15):

- Grouped beating (especially pairs or trios, but occasionally larger groups).
- Progressive lengthening of the PR interval until an impulse is not conducted (“dropped beat”).
- The longest cycle (of the dropped beat) is less than twice the length of the shortest (usually the impulse after the dropped beat).

The progressive lengthening of the PR interval gives the appearance of successive P waves retreating into the preceding QRS complexes. This highlights another feature of type I block, the concept of RP/PR reciprocity. This means that as the interval between the preceding R wave and the next P wave becomes shorter, the PR interval of the next cycle becomes longer until an impulse is dropped.

Type I second-degree AV block occurs in a variety of acute and chronic conditions (see Table 77-4) and usually requires no treatment. In the setting of acute myocardial infarction, this type of AV block is associated with inferior wall ischemia and a good outcome. Children with asymptomatic type I second-degree AV block may eventually develop complete heart block but usually remain asymptomatic because of adequate subsidiary pacemaker function. Carotid massage and increased vagal tone may worsen type I block, whereas atropine may improve conduction.

The Wenckebach phenomenon occurs in other conduction disturbances, including SA block, producing grouped impulses. Grouped impulses should always raise the question, “Is a Wenckebach mechanism present?” Not all grouped impulses are caused by this phenomenon (Box 77-5).

**Type II Second-Degree Atrioventricular Block.** Type II second-degree AV block, or Mobitz II block, is never a normal variant and implies a conduction block below the level of the AV node, usually in the His-Purkinje system. On the ECG, intermittent conduction of atrial impulses occurs without changes in the PR interval (Fig. 77-16). The QRS complex of conducted beats is often narrow, but wide-complex beats may result if infranodal conduction disturbances (e.g., bundle branch block) or escape impulses are present. Type II second-degree AV block is associated with a variety of acute and chronic diseases (see Table 77-4). Compared with type I second-degree AV block, type II block carries a worse prognosis. In acute myocardial infarction, type II AV block is associated with anterior wall ischemia and often progresses to complete AV block. This variety of block is further complicated by poor subsidiary pacemaker function and mandates that temporary pacing be readily available.

When the conduction ratio is 2:1, it may be impossible to distinguish type I from type II AV block on the ECG. The response to autonomic manipulation, however, can aid in this task. Atropine usually has no effect on the His-Purkinje system and may worsen the conduction ratio in type II AV block by increasing the number of atrial impulses without improving conduction (although clinical deterioration is not likely). Carotid sinus massage may transiently improve the conduction ratio (but not the overall condition) in type II AV block by slowing the conduction in the proximal AV node, allowing the lower conductive tissues to recover and be less refractory.

Pharmacologic treatment of type II AV block is not indicated. In the out-of-hospital setting, symptomatic type II second-degree AV block should be treated with transcutaneous pacing; in the ED, transcutaneous or transvenous pacing can be used. Immediate cardiology consultation should be sought for all patients, and none should be discharged to home unless the condition is chronic and without new symptoms.

**Third-Degree (Complete) Atrioventricular Block.** Third-degree, or complete, AV block is characterized by absent conduction of all atrial impulses (Fig. 77-17) and complete electrical AV dissociation. Not all AV dissociation represents complete heart block. For complete heart block to exist, the underlying atrial or junctional rhythm must be of a rate sufficient to overcome the action of any subsidiary infranodal pacemakers. For example, an accelerated junctional focus at a ventricular rate of 80 beats per minute (as a result of enhanced automaticity from catecholamine excess) may usurp the sinus node and become the dominant pacemaker. In this situation, the underlying sinus rhythm of less than 80 beats per minute would be manifest as regular P waves unrelated to the source of ventricular depolarization, the junctional rhythm. This junctional rhythm is not complete heart block because no underlying AV nodal conduction disorder is present. In a similar fashion, com-
A complete SA block coupled with a junctional or ventricular escape rhythm can be misidentified as complete AV block (see Fig. 77-13).

During complete heart block, the P waves and QRS complexes are present but are unrelated and occur at different rates. When the atrial and escape rates are similar, isorhythmic AV dissociation exists. This can be difficult to appreciate unless a long rhythm strip is examined and the P waves and QRS complexes are closely tracked. The duration of the QRS complex depends on the site of the escape rhythm pacemaker. Pacemakers above the His bundle produce a narrow complex, whereas pacemakers at or below the His bundle produce a wide-complex rhythm. The narrow-complex rhythms usually operate at a faster rate (45–60 beats/min) and respond to atropine and isoproterenol; the wide-complex escape rhythms are slower (30–45 beats/min) and are unaffected by autonomic drugs. When rapid P waves or fibrillatory waves are coupled with a slow and regular ventricular response, atrial tachycardia or fibrillation with third-degree heart block and an escape rhythm is present. This combination is commonly the result of digitalis toxicity.

Third-degree AV block can be congenital or acquired. In general, congenital third-degree AV block is associated with a narrow-complex escape rhythm and fewer symptoms. The fixed rate of the subsidiary pacemaker limits the ability to increase cardiac output, resulting in varying degrees of exercise intolerance. Acquired third-degree block is often the result of ischemia, drug therapy, or structural heart disease (alone or in combination). Acquired third-degree AV block often has a wide-complex escape rhythm and symptoms of hypoperfusion at rest or with minimal exertion.

In the field, the treatment of patients with third-degree AV block depends on the symptoms. Patients with clinical evidence of hypoperfusion are best treated with transcutaneous pacing. While atropine is often used in the field, it rarely helps or harms, usually simply altering conduction ratios without changing the escape rhythm. Asymptomatic patients should be rapidly transported with pacing readily available.

In the ED, the treatment includes close clinical assessment and pacing if there is any hypoperfusion. The patient should be admitted to an appropriate monitoring unit if acquired or symptomatic third-degree AV block is diagnosed. A transvenous temporary pacemaker is usually indicated but can be placed electively if the transcutaneous pacemaker is functioning well. Also, avoid type I antidysrhythmics since these can extinguish the escape rhythm.

This classification scheme has shortcomings. The conduction ratio depends on the atrial rate and the presence of under-
lying nodal pathology. A 2:1 conduction ratio does not mean worse conduction system disease than a 3:2 ratio, and not all 2:1 conduction is pathologic. For example, an atrial impulse rate of 300 complexes per minute (common in atrial flutter) presented to the AV node usually results in conduction of half the impulses, producing a ventricular rate of 150 beats per minute. This conduction ratio does not represent significant AV block because the AV node is responding normally and preventing excessive ventricular stimulation. Conversely, a sinus rhythm at a rate of 70 P waves per minute paired with a similar conduction ratio produces a ventricular rate of 35 beats per minute; this ratio clearly represents profound AV block. The term high-grade second-degree block is best applied to conduction disturbances that prevent physiologic ventricular response rates and not solely to higher conduction ratios.

**Extrasystoles and Parasystole**

*Extrasystoles*, defined as ectopic impulses that occur in addition to the underlying normal sinus rhythm, are present in most individuals when closely monitored. Certain specific extrasystoles may help identify patients with a poor prognosis when coupled with symptoms. Not all extra impulses are translated into mechanical contractions. Even without associated contractions, nonconducted impulses can trigger a secondary irregularity of the rhythm by interfering with conduction. In fact, the most common cause of a pause on the ECG is a nonconducted atrial extrasystole that resets the SA node.

The mechanism responsible for most extrasystoles is abnormal automaticity, although some can result from reentry or triggered automaticity. In general, ectopic impulses occur earlier in a cardiac cycle than the normal sinus impulse and are termed premature. By convention, the term contraction is applied to these extra impulses, although a true mechanical contraction may not always occur. The source of these ectopic impulses can be the atria, AV node, His-Purkinje system, or ventricles. Bigeminy occurs when an extrasystole follows every sinus beat, and trigeminy occurs when every third beat is extrasystolic (Fig. 77-18). These forms can occur with any of the three sources (atria, junction, or ventricles) and are usually benign rhythms.

The extrasystole and its preceding complex are referred to as the *couplet*, and the *coupling interval* refers to the period between these two beats. When the coupling interval in a given rhythm is constant (or “fixed”), a single focus is believed to be responsible for the extrasystoles. Although previously considered to be solely the result of reentry, fixed coupling does not reliably define the mechanism of ectopic impulse formation. There are three basic extrasystolic foci, along with a specific form of abnormal impulse generation and propagation called parasystole.

**Premature Atrial Contractions**

Premature atrial contractions (PACs) are often the precipitating event for a variety of dysrhythmias, including atrial fibrillation, atrial flutter, and SVT. Abnormal automaticity and atrial or AV nodal reentry are the most common causes of PACs. The diagnosis of PACs is made from the ECG, where an abnormal P’ wave is seen early within a cardiac cycle (Fig. 77-19). The P’ wave may be difficult to see if it is buried within the preceding T wave, although increasing the paper speed and use of an esophageal lead can help. Inverted P’ waves suggest an atrial source near the AV junction, where nearly normal P’ waves imply a focus near the SA node. If the P’ waves, P’R intervals, and coupling intervals are constant, a single focus is likely. Variations in these three characteristics are consistent with multiple foci. Either the left or right atrium can be the source of PACs.

Most PACs depolarize the sinus node, which resets the intrinsic sinus node rate. On the ECG, the P-P interval after a conducted PAC is equal to the P-P interval of the cycle preceding the PAC. Because of this adjustment of the sinus cycle, the R-R interval surrounding the ectopic beat is less than twice the intrinsic R-R cycle length (see Fig. 77-19). This is referred to as a noncompensatory pause, a hallmark of PACs. Occasionally, PACs do not depolarize the sinus node, and a compensatory

---

*Figure 77-18. Ventricular bigeminy.*

*Figure 77-19. Premature atrial contractions.*
pause may result. Fully compensatory pauses are more commonly seen with premature ventricular contractions (PVCs). Table 77-5 lists ECG features to help distinguish PACs from PVCs.

If it is conducted to the ventricles, a PAC results in a QRS complex that occurs earlier than the expected sinus QRS complex. The QRS complex from a PAC is narrow and identical to the sinus rhythm complex unless aberrant conduction occurs (Fig. 77-20). Aberrancy is likely to occur if a PAC arrives early within the cardiac cycle, with an RBBB pattern commonly seen on the ECG. Since bundle conductivity depends on the previous cycle length, a PAC that follows a long cardiac cycle (reflected as a preceding long R-R interval) may also be aberrantly conducted because the bundles require more time to repolarize. In the latter setting, aberrant conduction occurs because of the relatively early arrival of the PAC for the given cycle length. This “long/short” aberrant conduction is called the Ashman phenomenon and can occur with any irregular atrial rhythm, including PACs and atrial fibrillation.

A PAC is the most common cause of a pause on the ECG. Although the source of this type of pause is obvious when a PAC is conducted, nonconducted PACs are frequently responsible for pauses. In this situation, the sinus node is depolarized by the PAC, causing an interruption and resetting of the regular rate. If the same extrasystolic impulse reaches the AV node or infranodal conducting system during the refractory period, no ventricular depolarization is possible. This combined sinus node reset with a nonconducted atrial extrasystole creates the pause seen on the ECG. Often the PAC responsible for a pause falls within the previous T wave and is not visible on the ECG. On rare occasions an extremely late PAC can cause atrial depolarization in combination with the sinus node impulse. The P′ waves in these cases represent a fusion complex and have qualities of both impulses.

The management of PACs is based on recognition with no need for specific therapy. Underlying causes, such as catecholamine excess, hypoxemia, myocardial ischemia, heart failure, and acid-base or electrolyte imbalance, should be treated.

### Table 77-5 Features to Distinguish Premature Atrial Contractions with Abnormal Conduction from Premature Ventricular Contractions

**Figure 77-20.** Premature atrial contractions (PACs) with noncompensatory pauses and one aberrantly conducted impulse (upper strip). Note that both conducted and nonconducted PACs reset the sinus node, with the latter creating a pause.
**Causes of Premature Ventricular Contractions and Ventricular Tachycardia**

- Acute or previous myocardial infarction/ischemia
- Hypokalemia
- Hypoxemia
- Ischemic heart disease
- Valvular disease
- Catecholamine excess
- Other drug intoxications (especially cyclic antidepressants)
- Idiopathic causes
- Digitalis toxicity
- Hypomagnesemia
- Hypercapnia
- Class I/antidysrhythmic agents
- Ethanol
- Myocardial contusion
- Cardiomyopathy
- Acidosis
- Alkalosis
- Methylxanthine toxicity

*Relative increase in sympathetic tone from drugs (direct or indirect) or conditions that augment catecholamine release or decrease parasympathetic tone.

†Isolated premature ventricular contractions (PVCs) can occur in up to 50% of young subjects without obvious cardiac or noncardiac disease; however, multiform and repetitive PVCs and ventricular tachycardia are rarely seen in this population.

Fully compensatory pauses and aberrant conduction occur more often with PJCs than with PACs. The causes and treatment of PJCs are the same as those of PACs.

**Premature Ventricular Contractions**

PVCs can occur in a variety of pathologic and nonpathologic states. Their major importance is related to the clinical scenario accompanying their presence and the risk of more serious ventricular dysrhythmias, such as ventricular tachycardia and fibrillation. Extrasystoles that occur during ventricular repolarization (the R-on-T phenomenon) are believed to carry a higher risk of precipitating ventricular tachycardia, although the magnitude of this effect is debated. Other data suggest that PVCs occurring during the next atrial depolarization (the R-on-P phenomenon) carry as high or a higher risk of precipitating serious ventricular dysrhythmias than R-on-T PVCs.

PVCs can be caused by varying mechanisms (Box 77-6), including reentry, abnormal automaticity, and triggered afterdepolarizations. Classically, PVCs appear on the ECG as wide QRS complex extrasystoles (>0.12 second) unassociated with a preceding P wave (Fig. 77-21). In a single lead, a PVC may appear as a narrow QRS complex. This narrow complex occurs if the wave of depolarization is traveling directly perpendicular to the ECG lead and underscores the need to examine multiple leads to identify PVCs accurately. Although P waves from nonconducted sinus impulses may be seen on the ECG, these should have no consistent relationship with the QRS complexes from the PVCs. Rarely, retrograde conduction of PVCs can produce an inverted P' wave after each QRS complex. PVCs usually cause a fully compensatory pause, with the resulting RR interval encompassing the PVC equal to twice the intrinsic RR interval length (see Fig. 77-21). Rarely, noncompensatory or subcompensatory pauses can be seen with PVCs and are associated with retrograde conduction and sinus node depolarization. Interpolated PVCs refer to another rare instance when the underlying sinus rhythm is unaffected by a PVC (Fig. 77-22).

The structure of the QRS complexes depends on the origin of the impulse. PVCs with a left bundle branch appearance result from a wave of depolarization beginning in a right ventricular source and vice versa. Multiform (or “multifocal”) PVCs refer to ventricular extrasystoles from more than one source and appear as varying QRS complex structures. When a PVC depolarizes the ventricles at a similar time as a conducted atrial beat, a fusion QRS complex is seen (Fig. 77-23). Identification of fusion QRS beats indicates the presence of PVCs.

PVCs produce abnormal repolarization as a direct result of the abnormal depolarization of the ventricles. Secondary T wave abnormalities refer to the repolarization changes seen as a result of pathologic depolarization and are seen with PVCs along with bundle branch blocks and left ventricular hypertrophy. These secondary T wave changes consist of widening and deflection opposite of the main QRS deflection (see Fig. 77-21). Primary T wave abnormalities refer to changes in ventricular repolarization caused by underlying cardiac disease (such as ischemia) and are not solely the result of depolarization abnor-
malities. Primary T wave changes often consist of T wave deflection in the same direction as the main QRS vector.

The pattern of PVCs is commonly classified by the Lown criteria (Table 77-6). In general, these criteria are intended to distinguish benign PVCs from those likely to degenerate into ventricular tachycardia and ventricular fibrillation. After myocardial infarction, PVCs in Lown classes 3 to 5 carry a high risk for these malignant ventricular dysrhythmias and sudden death, with class 4 having the highest risk. The use of this classification system in other patients with PVCs does not predict the risk of morbidity and mortality. PVCs are found in healthy young patients and their frequency generally increases with age.

Therapy for PVCs is directed toward correcting the underlying cause, especially if ischemia, electrolyte imbalance, or drug overdose is evident. Often, PVCs are not symptomatic aside from a sensation of palpitations. In the absence of ischemia, asymptomatic PVCs alone rarely require antidyssrhythmic therapy. Although lidocaine can lessen or abolish PVCs in the setting of acute myocardial infarction, it is recommended only when PVCs in Lown classes 3 to 5 are present or close monitoring and rapid defibrillation capabilities are not readily available. Even in ischemic settings, most clinicians only treat sustained PVC runs.

The need for intravenous delivery limits the use of all class I agents except lidocaine in the out-of-hospital setting. The treatment of PVCs is rarely indicated in the ED. In the ED, alternative agents such as amiodarone and procainamide are options for the few indications, although lidocaine remains an acceptable alternative despite the rare concern of heart block in ischemia. In selected cases, beta-blockers (e.g., for catecholamine-induced PVCs and those occurring after myocardial infarction) and calcium channel blockers (after reperfusion therapy) can diminish PVC frequency and decrease the risk of ventricular fibrillation and ventricular tachycardia. Magnesium sulfate (2–4 g IV over 10–20 minutes) can also diminish the frequency of PVCs, particularly in the setting of acute myocardial ischemia.

Patients with symptomatic or frequent PVCs and syncope, presyncope, dyspnea, or chest pain should be monitored. This can be done (with an ambulatory monitor if otherwise asymptomatic) after considering potential causes listed in Box 77-6.

Parasystole

Parasystole occurs when two separate pacemakers compete to produce ventricular depolarization in the absence of structural conduction disease. The latter distinguishes parasystole from high-grade incomplete or complete AV block. In addition to the sinus node, the usual source of the second pacemaker is the ventricular conductive or contractile tissues, although atrial and junctional pacemakers can also cause parasystole. The key point in identifying the competing pacemaker is that it functions like an artificial fixed-rate pacemaker, producing impulses irrespective of the sinus node activity. The second pacemaker displays an entrance block, which prevents any outside impulse from depolarizing the area and resetting the rhythm.

Ventricular parasystole has five characteristics on the ECG in addition to its wide QRS extrasystolic complexes and fixed rate (Box 77-7 and Fig. 77-24). One hallmark of parasystole is
A fixed interectopic interval. In this, the R’R’ intervals are the same throughout a rhythm strip or follow a similar denominator. This is a direct result of the protected parasystolic focus. If all impulses exiting this focus find the conducting system nonrefractory, a fixed interectopic interval is observed. If the conducting tissues are refractory (usually from recent conduction of a sinus impulse), no ventricular depolarization is seen on the ECG, yet the protected parasystolic focus continues to fire at the same rate. If the next impulse from the parasystolic focus finds nonrefractory conducting tissues, the interectopic interval is equal to two times the basic cycle length. If the first and second parasystolic impulses are not conducted but the third in a series finds nonrefractory tissues, the interectopic interval is three times the basic cycle length. For example, based on a 1-second interval, ventricular parasystole may have R’R’ intervals in multiples of this interval (e.g., impulses seen 1, 2, or 3 seconds apart at various times).

Ventricular parasystole is usually the result of an altered automatic mechanism and does not have the serious implications that frequent PVCs have even when an R-on-T phenomenon is seen. Ventricular parasystole may be difficult to distinguish from frequent PVCs in the field because it requires close observation of a prolonged rhythm strip with multiple leads. Fusion QRS complexes may be seen but are not essential to the diagnosis. Ventricular parasystole is usually a benign rhythm, with treatment similar to that of non-ischemia-related PVCs.

Atrial and junctional parasystoles are rare and are more difficult to diagnose. They can be identified when P’ waves or junctional impulses are seen throughout an underlying sinus rhythm with a fixed interectopic interval. As with ventricular parasystole, the P’-P’ intervals or junctional RR intervals should be the same or in multiples of a common interval. Atrial and junctional parasystoles are usually benign and require no specific emergency therapy.

**Narrow-Complex Tachycardia**

*Narrow-complex tachycardia* are rhythms with a QRS complex duration of less than 0.12 second and a ventricular rate of greater than 100 beats per minute. Although virtually all narrow-complex tachydysrhythmias originate from a focus above the ventricles (with the rare exception of a very high His bundle rhythm), the term supraventricular tachycardia is conventionally used to denote the rhythms aside from sinus rhythm, atrial tachycardia, atrial fibrillation, and atrial flutter. The atrial depolarization waves may be difficult to appreciate on the ECG, especially if the ventricular response rate is over 150 beats per minute. The use of multiple-surface leads, increased paper speed, an esophageal lead, or vagal maneuvers can help identify the atrial depolarization waves and diagnose the source of the dysrhythmia. Also, atrial or junctional parasystole can create a narrow-complex tachycardia, termed *pseudotachycardia* because neither focus has a ventricular rate greater than 100 beats per minute.

One ECG feature that can help distinguish the source of a tachydysrhythmia is the location of the P waves and the regularity of the QRS complexes. If nearly normal-appearing atrial depolarization waves precede each QRS complex and the underlying pattern is regular, a sinus rhythm, atrial flutter, or single-focus atrial tachycardia is commonly present. If a completely irregular (or chaotic) pattern of QRS complexes is seen, atrial fibrillation, multifocal atrial tachycardia, or another atrial rhythm with varying conduction is possible (Box 77-8). The identification of atrial depolarization waves and the appearance of irregularity or regularity can be deceiving within any short rhythm strip.

The treatment of each narrow-complex tachycardia is based on the specific rhythm and symptoms. In general, class II (beta-adrenergic blockers) and IV agents (calcium channel blockers) are used to slow AV nodal conduction. These agents may terminate certain dysrhythmias, especially AV nodal reentry. Adenosine transiently slows AV nodal conduction and can help diagnose or treat certain rhythms. Classes IA and IC agents are useful in converting other narrow-complex tachycardias (e.g., atrial flutter and fibrillation) to a sinus rhythm.

After identifying the specific dysrhythmia during an episode, the underlying cause of the tachycardia should be sought. Hypovolemia is a frequent cause of a narrow-complex tachycardia, especially in the young. Fever, anemia, hypoxemia or impaired oxygen delivery (including abnormal hemoglobin states), relative sympathetic excess, drug intoxication, endocrinologic disease (especially thyroid), metabolic derangements, ischemia, infections, and inflammatory causes (including myocarditis and pericarditis) are other considerations.
Sinus Tachycardia

Sinus tachycardia is characterized by a narrow-complex regular rhythm at a ventricular rate of greater than 100 beats per minute. The P waves are upright in all leads but aVR and the appearance of each is consistent (Fig. 77-25). The PR and PP intervals are usually constant, but both may shorten as the rate increases. Increasing vagal or decreasing sympathetic tone decreases the rate of impulse formation and conduction in a graded continuous manner. Conversely, sinus tachycardia can result from increased catecholamine tone or decreased vagal stimulation.

Functionally, sinus tachycardia is a response to physiologic stress and is intended to increase cardiac output. This response can be compensatory for a relative lack of perfusion or oxygen delivery, such as congestive heart failure, pulmonary embolism, hypovolemia, anemia, or sepsis. It can also occur in non-hypoperfusion states when a relative sympathetic excess exists. Treatment is based on the recognition and treatment of the underlying cause. Although anxiety or pain can cause sinus tachycardia in patients, this is a diagnosis of exclusion after a careful search for evidence of the aforementioned physiologic causes of tachycardia.

Sinus tachycardia can be easily mistaken for other causes of a regular narrow-complex tachycardia, especially in young patients, and the converse can occur (e.g., regular atrial flutter at a rate of 150 beats per minute mistaken for sinus tachycardia). Infants and young children can easily attain ventricular rates of 170 to 225 beats per minute with an episode of hypovolemia-induced sinus tachycardia. This may be mistaken for a paroxysmal atrial or junctional tachycardia, with disastrous consequences if a rate-controlling drug is given. Adults do not often reach a rate above 170 beats per minute because of the braking properties of the AV node.

Specific antidysrhythmic therapy for sinus tachycardia is almost never indicated. If the patient is symptomatic or if the risk of precipitating myocardial ischemia is high, the use of a beta-blocker is warranted only after all possible primary causes are treated or eliminated from consideration.

Atrial Tachycardia and Multifocal Atrial Tachycardia

Atrial tachycardia refers to any rapid dysrhythmia from a non-sinus focus above the AV node. Atrial tachycardia can be gradual in onset (suggesting an abnormal automatic mechanism) or abrupt (suggesting a reentrant mechanism). The hallmark of this dysrhythmia on the ECG is a narrow-complex tachycardia at a ventricular rate above 100 beats per minute, with each QRS complex preceded by a P′ wave that is morphologically different from the sinus P wave (Fig. 77-26). If the P′ wave is inverted, a low atrial source is likely. The P′-R interval can be normal or abnormal and is usually constant unless more than one focus is involved. Generally, the conduction ratio is 1:1, but this can vary, especially as the atrial rate increases. If no ECG tracing of the normal sinus rhythm is available, single-focus atrial tachycardia can be indistinguishable from sinus tachycardia.

Paroxysmal atrial tachycardia (PAT) is an intermittent dysrhythmia with an abrupt onset and termination, often seen in children and young adults without concomitant SA node disease. PAT is usually reentrant in origin, as opposed to nonparoxysmal (sustained) atrial tachycardia (NPAT), which is often automatic in nature. PAT can be precipitated by a PAC, or rarely by a PVC, and often originates and terminates abruptly. Other causes of PAT and NPAT include electrolyte and acid-base disturbances, drug toxicity, fever, and hypoxemia. NPAT with varying or complete AV block is classically seen in digitalis toxicity.

Multifocal atrial tachycardia (MAT) is a subset of atrial tachycardia, with more than two foci of impulse formation. On the ECG, at least three distinctly different P waves with varying P′-R, R-R, and P-P′ intervals are seen (Fig. 77-27). In addition to the causes just listed for PAT, MAT is often associated with pulmonary disease and hypoxemia, either directly from these conditions or as a result of beta-adrenergic agonist or chronic methylxanthine treatment. MAT often resolves when hypoxemia is resolved with supplemental therapy and when other therapies are optimized. MAT is easily confused for atrial fibrillation, since irregularity exists in both, with MAT being much less common.

Correcting the underlying primary disturbance treats PAT, NPAT, and MAT. If the patient is symptomatic and without evidence of instability, or if concerns about precipitating myocardial ischemia are present, treatment with a beta-blocker or calcium channel blocker can be begun in the absence of hypotension. Magnesium (2–4 g IV) is a second-line agent for PAT and MAT. Although adenosine may slow the ventricular rate or occasionally extinguish atrial tachycardias, these rhythms

Figure 77-25. Sinus tachycardia.
often recur because of the short therapeutic effect of this drug. Overdrive transvenous atrial pacing can be used if a reentrant mechanism is suspected and drug treatment fails.

In general, electrical treatment is rarely needed in PAT and MAT. If hypotension or other manifestations of instability exist, synchronized cardioversion with sedation at 50 to 100 J can be performed. Cardioversion is not useful in refractory cases of MAT because the dysrhythmia is likely to recur if no other treatment is employed. When it is the result of digitalis toxicity, PAT and MAT should be treated by correcting hypokalemia if it exists, followed by administration of magnesium and digitalis antibody fragments. Emergency cardioversion should be avoided if possible in this setting.

Atrial Flutter

The most accepted characteristics of atrial flutter are (Fig. 77-28):

- A regular atrial depolarization rate of 250 to 350 atrial complexes per minute—a rate of 300 beats per minute is classic though not universally present.
- Distinct ECG manifestations of abnormal atrial depolarizations in a “saw tooth” appearance. These are referred to as flutter waves and are best seen in leads II, III, aVF, and V1–2.
- Frequent 2:1 or 4:1 AV conduction ratio, although any ratio may be seen. The 2:1 ratio with an atrial rate of 300 beats per minute accounts for the classic (although not exclusive) ECG appearance of atrial flutter as a narrow-complex tachycardia with a regular ventricular rate of 150 beats per minute.

Most experimental data suggest a reentrant mechanism for atrial flutter, although some patients may display an abnormal automatic mechanism. In the ED, it is easy to mistake atrial flutter for sinus tachycardia, especially if the flutter waves resemble normal P waves or a nonclassic ventricular rate is present.

Atrial flutter is often associated with structural heart disease, heart failure, valvular dysfunction (especially mitral), or thyroid disease. The clinical importance of atrial flutter is primarily the result of symptoms caused by the ventricular response rate, including palpitations, syncope, presyncope, hypotens-
sion, chest pain, and heart failure. If accompanied with an AV block, especially a Wenckebach mechanism, atrial flutter may have irregular ventricular rates like atrial fibrillation. Rarely, high-grade AV conduction block can result in a very fast atrial rate but clinical bradycardia.

In stable patients, ventricular response rates can be controlled with an intravenous calcium channel blocker or a beta-adrenergic blocker. Diltiazem is often favored, although in practice there is little difference in the effects and complication rates among these agents in patients without overt ventricular failure. Digitalis can be used as a second-line agent or in those with mild tachycardia and preexisting congestive heart failure. Magnesium (2–4 g IV) is an adjunctive or third-line therapy to control the ventricular response rate. The major value of adenosine may be in unmasking flutter waves in a narrow-complex tachydysrythmia, helping to identify the underlying rhythm correctly. Hence, its role may be diagnostic, but it is not therapeutic.

All AV nodal conduction slowing agents, including calcium channel blockers, beta-adrenergic blockers, adenosine, and digitalis, should be avoided in patients with atrial flutter and a suspected accessory pathway because these agents primarily block AV nodal conduction and may enhance anterograde conduction in the accessory path. Rapid ventricular response rates (especially >200 beats/min in an adult) are a clue to the possibility of an accessory pathway because normal AV nodal tissues rarely allow a ventricular response rate of more than 150 to 165 beats per minute. The use of any predominantly AV nodal blocking agent in the presence of an accessory pathway and atrial flutter or fibrillation may allow unbridled rapid ventricular response rates and precipitate ventricular fibrillation.

Type IA agents (especially procainamide) can convert atrial flutter if the previously mentioned drugs fail, or they may be used to prevent recurrence in an outpatient setting. The type III agents amiodarone and ibutilide are alternative primary converting agents. Finally, synchronized electrical cardioversion with sedation, beginning at 25 to 50 J, is effective in terminating atrial flutter in refractory or unstable patients. If electrical therapy is successful but atrial flutter recurs, a type IA or IC agent should be used before repeated electrical cardioversion to help prevent this from occurring again.
Atrial fibrillation is the result of chaotic depolarization of atrial tissues. This chaotic activity can lead to reduced cardiac output from a loss of coordinated atrial contractions and a rapid ventricular rate, both of which may limit the diastolic filling and stroke volume of the ventricles. Atrial fibrillation may be paroxysmal or chronic; the paroxysms may last for minutes to days. On the ECG, fibrillatory waves are seen and accompanied by an completely irregular QRS pattern, the hallmark of atrial fibrillation (Fig. 77-29). These fibrillatory waves are best seen in the inferior leads or lead V1 and are described as fine to coarse on the basis of their amplitude. Atrial fibrillation is the result of multiple microreentry circuits, creating 300 to 600 atrial impulses per minute.

The QRS complexes are usually narrow unless an underlying bundle branch block is present. The Ashman phenomenon can cause isolated or repeated aberrant ventricular conduction, usually in an RBBB pattern (Fig. 77-30). These Ashman beats can be mistaken for PVCs if the long-short cycle sequence is not recognized. The ventricular response rate depends on the conduction path and ratio, with the normal AV node maximal response rate being no greater than 150 to 170 beats per minute. As noted with atrial flutter, the presence of a chaotic rhythm (irrespective of the QRS duration) at a ventricular rate of more than 200 beats per minute strongly suggests atrial fibrillation coupled with conduction down an accessory pathway. This rhythm may deteriorate to ventricular fibrillation,

\[\text{Atrial fibrillation with rapid ventricular response.}\]
Causes of atrial fibrillation

Rhythms with varying conduction) and the recognition of it from other chaotic rhythms (primarily MAT or other atrial syndrome strongly suggests digitalis toxicity. 

Atrial fibrillation shows characteristics of both rhythms on ECG. It may be manifested as fine fibrillatory waves with irregular QRS complexes intermixed with flutter waves and a stretch of regular QRS complexes. Rapid atrial fibrillation followed by sinus bradycardia in an elderly patient suggests the aforementioned bradycardia-tachycardia syndrome. Finally, irregular atrial fibrillatory waves coupled with regular narrow or wide QRS complexes may represent atrial fibrillation coupled with complete heart block and an accelerated junctional or ventricular rhythm; this syndrome strongly suggests digitalis toxicity.

The treatment of atrial fibrillation is based on distinguishing it from other chaotic rhythms (primarily MAT or other atrial rhythms with varying conduction) and the recognition of any underlying causes and symptoms. Asymptomatic atrial fibrillation at a ventricular rate of 100 beats per minute or less requires no specific emergency therapy. Patients who are unstable from acute rapid atrial fibrillation should receive sedation and synchronized cardioversion starting at 50 to 100 J. Electrical cardioversion is not associated with an increased risk of malignant ventricular dysrhythmias in patients receiving digitalis unless clinical or laboratory evidence of toxicity coexists.

In the ED, the therapeutic course chosen depends on the aforementioned principles plus the duration of the dysrhythmia. Both chronic and paroxysmal atrial fibrillation are associated with atrial thrombus formation and embolic events. Chronic but rapid atrial fibrillation is best managed by treating any trigger (notably volume deficits, infection, or decompensated heart failure) and rate control if needed. Embolic risk increases with the duration of atrial fibrillation and when there is underlying valvular disease or chamber enlargement. Prolonged outpatient attempts to establish or maintain a sinus rhythm in patients with recurrent atrial fibrillation do not offer a clear benefit compared with rate control.

Patients with new-onset atrial fibrillation of more than 72 hours’ duration should receive ED rate control if needed. Before considering cardioversion in this group through any means, a search for atrial clot or empiric anticoagulation is needed. This usually occurs in an observation or formal admission setting. Clot and embolism can develop during fibrillation and for days after conversion, the latter related to stunned myocardium after restoration of a sinus rhythm.

In stable patients with new-onset atrial fibrillation for 72 hours or less, ventricular rate control first is recommended. After carefully assessing the functional implications (seeking evidence of myocardial ischemia, heart failure, syncope, or other symptoms directly attributed to the dysrhythmia), cardioversion may be undertaken, often in consultation with a cardiologist.

Intravenous calcium channel blockers (diltiazem or verapamil) or beta-adrenergic blockers are first-line rate-controlling agents in atrial fibrillation. As in atrial flutter, the relative effectiveness and complication rates in clinical practice between these agents are similar absent overt heart failure; titration is the most important guiding principle.

Beta-adrenergic blockers are particularly effective in atrial fibrillation secondary to hyperthyroidism or catecholamine excess. Digitalis is a second-line agent for ventricular rate control because of its relatively slow onset of action. Calcium channel and beta-adrenergic blockers, adenosine, and digitalis are not indicated for patients in atrial fibrillation with an accessory pathway because of the risk of precipitating ventricular fibrillation.
Intravenous magnesium sulfate (2–4 g over 2 minutes) is an adjunctive or third-line therapy to decrease the ventricular response rate. As with its use in atrial flutter, adenosine is not indicated as a primary therapy because of its short duration of effect. For outpatient rate control, calcium channel and beta-adrenergic blockers are preferred over digitalis in patients without contraindications.

Again, despite intuition, there appears to be no long-term benefit of converting atrial fibrillation to sinus rhythm, as opposed to rate control alone. This is especially true for older patients. However, it may be appropriate to attempt pharmacologic cardioversion for younger patients who present with a first known episode of atrial fibrillation of less than 72 hours’ duration. Pharmacologic cardioversion of atrial fibrillation is best accomplished with procainamide, amiodarone, flecainide, propafenone, or ibutilide. Each has conversion rates around 50 to 70%, although there may be a modestly better success rate with ibutilide. Flecainide and propafenone are reserved for patients without significant structural heart disease, hypertension, ischemia, or heart failure. In other words, these agents may be used when the patient’s only indication of heart disease is atrial fibrillation (“lone” atrial fibrillation). In all other cases, procainamide, amiodarone, or ibutilide is an appropriate choice. A calcium channel or beta-adrenergic blocker should be given before a type IA agent to control the ventricular rate, with a target of 100 to 120 beats per minute (Box 77-10). This approach may limit any increase in the ventricular rate from the type IA agent. Irrespective of the route and specific agents chosen, pharmacologic cardioversion requires close monitoring and observation. If a class IA or III agent fails, one should not switch to agents of another class for several hours to avoid complications.

Type IC agents (flecainide and propafenone) are not available for intravenous use in the United States (but are used in Europe for this indication) and therefore have a limited role for emergency management of atrial fibrillation. Vernakalant is an investigational, atrial-specific type IC agent that may become a useful tool for acute atrial fibrillation conversion, with fewer conductive side effects. One European trial noted success with oral propafenone or flecainide in a single dose “pill in the pocket” method. In this approach, patients with previous atrial fibrillation paroxysms are given a dose of either agent, taking it when symptomatic and irregular palpitations occur. This strategy can convert some very symptomatic patients to a sinus rhythm within hours and obviate an ED visit or hospitalization.

Electrical cardioversion (with 50–100 J) is indicated if the previously described measures fail to convert symptomatic atrial fibrillation and in unstable patients. Although a synchronized countershock is recommended, the irregularity may require delivery of an unsynchronized countershock. Electrical therapy converts 85 to 90% of new-onset, stable, and nonvalvular atrial fibrillation.

Admission criteria for a patient with atrial fibrillation include instability, myocardial ischemia, worsened heart failure, or symptomatic recurrence in the ED. Traditionally, all patients with new-onset atrial fibrillation were admitted to “rule out” causes such as myocardial ischemia and pulmonary embolism. These diagnoses are rarely occult, and selective discharge of patients in the absence of clinical evidence of acute coronary ischemia, new valve dysfunction, acute lung illness (including pulmonary embolism), or thyroid disease is acceptable after ED observation and with close follow-up. While electrical conversion previously mandated admission, it may be possible to discharge after observation absent other admission triggers.

**Supraventricular (Atrioventricular Nodal) Tachycardia**

These dysrhythmias are often referred to as paroxysmal supraventricular tachycardia (PSVT or simply SVT), although the precise term is paroxysmal junctional tachycardia (PJT). For the purposes of this discussion, we will use the more common term, PSVT. ECG diagnosis is based on the presence of a narrow-complex regular tachycardia without preceding atrial depolarization waves (Fig. 77-31).

PSVTs produce retrograde atrial depolarization and a P' wave, but these P’ waves are usually buried within the QRS complex. P’ waves may be located anywhere in relation to the QRS complex and assume either a normal or abnormal structure. The location of the P’ waves can be useful in defining the electrophysiologic source of a PSVT and help distinguish it from other causes of a regular narrow-complex tachycardia (Fig. 77-32).

Among all patients with a regular PSVT, reentrant PSVT (also termed AV nodal reentry) is the most common type. The alpha pathway within the AV node is used for anterograde conduction in 90% of cases of sustained PSVT and accounts for the common finding of P waves buried within the QRS complexes (see Fig. 77-32). Clinically, patients experience the abrupt onset of a regular tachycardia at a ventricular rate of 120 to 200 beats per minute. A PJT or PAC often initiates PSVT. Termination is also abrupt, from increased vagal tone, drug therapy, or spontaneous conversion. PSVT at a rate of more than 225 beats per minute is rare, and suggests an accessory pathway syndrome. All “regular” narrow-complex tachycardias (QRS duration <0.10 second) are treated in the same way, whether or not a PSVT or accessory pathway syndrome is responsible. As noted, sinus tachycardia may be mistaken for SVT or PSVT in infants and young children.

**Nonparoxysmal (or sustained) junctional tachycardia** (NPJT) is usually the result of an automatic mechanism, with gradual onset and termination. NPJT rarely exceeds a ventricular rate of 130 beats per minute. Compared with PJT, NPJT is more

Preexcitation and Accessory Pathway Syndromes

Preexcitation refers to depolarization of the ventricular myocardium earlier than would occur by conduction of an impulse through the AV node. This implies the existence of a pathway from the atria to the ventricular myocardium in addition to the AV node, hence the term accessory pathway. These terms are related but not interchangeable because not all accessory paths are used to activate the ventricles early. Wolff-Parkinson-White (WPW) syndrome is the classic accessory pathway syndrome, although it probably represents a group of pathologic conditions. The clinical hallmark of this syndrome is paroxysmal tachycardia at a ventricular rate of 150 to 300 beats per minute, the direct result of the loss of the normal AV node conduction restraint. Any tachycardia in an adult at a ventricular rate greater than 200 beats per minute should raise the suspicion of an accessory pathway syndrome.

The classic WPW syndrome consists of tachycardia with the following three features (Fig. 77-33):

- A short P-R interval (<0.12 second)
- QRS duration greater than 0.10 second
- A slurred upstroke to the QRS complex, referred to as a delta wave

often associated with underlying heart disease, electrolyte imbalance, or excess catecholamine states.

Asymptomatic junctional tachycardia at a rate less than 120 beats per minute does not require specific therapy aside from correcting any underlying abnormalities. Stable symptomatic patients with rates greater than 120 beats per minute are most often treated initially with adenosine. The adult dose is 6 mg, followed by 12 mg, which can be repeated, if conversion does not occur. Conversion with adenosine is successful in 85 to 90% of cases. Similar results can be obtained with a calcium channel blocker or a beta-adrenergic blocker. Although adenosine produces initial success rates similar to those seen with diltiazem or verapamil, recurrence rates may be higher because of the short serum half-life (10 seconds; see Miscellaneous Agents, Adenosine). Calcium channel blockers and adenosine are safe and effective in out-of-hospital treatment of PSVT. Vagal maneuvers, especially Valsalva maneuver or carotid sinus massage, may effectively terminate the PSVT without pharmacologic intervention. In certain cases, patients can be taught how to do this at home.

Blood pressure must be monitored closely to avoid excessive hypotension, making electrical cardioversion a better choice in patients with severe hypotension during the PSVT. Type IA and IC agents may be used to prevent the recurrence of PSVT, particularly in individuals who cannot tolerate calcium channel or beta-blockers. Cardioversion (ideally synchronized) with 50 to 100 J is the best treatment for unstable patients with PSVT or NPJT.

Most patients can be discharged if the PSVT is terminated. Oral therapy with a class II or IV agent is an option for those with frequent symptomatic episodes of PSVT, but this decision is best made in consultation with the physician who will be providing ongoing care for the patient. Patients with serious underlying medical illnesses, recurrent or poorly controlled dysrhythmias, or evidence of instability or cardiac ischemia should be admitted to the hospital or ED observation unit. Some patients requiring electrical cardioversion may be admitted to the hospital, although an otherwise healthy patient who is easily cardioverted without recurrence can be considered for discharge with appropriate follow-up. Referral for thyroid testing, ambulatory monitoring, electrophysiology studies, and potential ablation may be considered if the problem is recurrent or associated with profound symptoms.
The short P-R interval is the result of the absent AV node conduction delay, and the delta wave occurs because of early activation of the ventricular myocardium. Although the WPW syndrome typically has a prolonged QRS duration as a result of the delta wave, the QRS duration commonly varies with the location and conduction direction of the accessory pathway. Pathways inserting into infranodal conducting tissues can produce a near-normal QRS complex, whereas those inserting in the nonconductive tissues produce a wide QRS complex with an abnormal structure. If this classic triad is present, secondary T wave changes (a deflection opposite the main QRS vector) are seen.

Multiple possible connections between the atria and ventricles can create an accessory path in WPW syndrome (Fig. 77-34), with up to 13% of patients having more than one anomalous AV path. The Kent fibers are the single most common accessory pathway. Historically, WPW syndrome was divided into left-sided (QRS mostly positive in V1, type A) and right-sided (QRS mostly negative in V1, type B) paths, with the latter being more accessible to surgical ablation. With the advent of catheter radiofrequency ablation, this classification is no longer relevant.

The accessory path(s) participate in a reentry circuit that produces or sustains the tachycardia. The AV node often constitutes one limb of these circuits. When the QRS complex is narrow and a delta wave is absent, the AV node is being used for anterograde conduction to the ventricles and the accessory path is used for retrograde conduction, termed an orthodromic tachycardia. Conversely, if the QRS complex is wide and a delta wave is present, the accessory pathway is being used as the anterograde limb and the AV node as the retrograde limb of the reentry circuit, termed an antidromic tachycardia. The majority of symptomatic patients with WPW syndrome have a regular orthodromic tachycardia, making detection of the syndrome difficult in the ED. Conversely, asymptomatic WPW syndrome is usually discovered when a delta wave or waves and wider QRS complex of antidromic WPW syndrome are seen on the ECG.

Patients with WPW syndrome often have one or more of the classic features missing on the surface ECG, especially if a sinus rhythm is present at the time of evaluation. WPW syndrome is present in 0.1 to 0.3% of the population, with men affected twice as often as women. On the basis of this prevalence, it is estimated that only 25 to 50% of patients with WPW syndrome become symptomatic. WPW syndrome is associated with a variety of conditions, although up to 70% of patients have no underlying heart disease (Box 77-11). In those without underlying heart disease, especially if WPW syndrome is discovered in the absence of symptoms, the prognosis is excellent, with an extremely low risk of sudden death.

The presenting rhythm in symptomatic patients with WPW syndrome is usually a reentrant tachycardia (70–80%), although atrial fibrillation can be seen in 10 to 30% of patients. Emergency treatment depends on the following three observations:

- **Symptoms of instability**
- **QRS duration or delta wave presence**
- **QRS regularity or irregularity**

Unstable patients, irrespective of the QRS duration or regularity, should be cardioverted (synchronized preferred) with 50 to 100 J (0.5–2 J/kg for children) with sedation if time permits.

A regular orthodromic (narrow QRS complex) tachycardia is the single most common presentation of an accessory pathway syndrome (and often not recognized as an accessory pathway syndrome) and is treated in the same way as PSVT. Adenosine, calcium channel blockers, beta-adrenergic blockers, and procainamide are all suitable for first-line therapy if vagal maneuvers fail. Procainamide may be preferable as the primary therapy for all stable patients with the WPW syndrome with prolonged QRS complexes because of its effectiveness and safety irrespective of the conduction pathway. Digitalis, amiodarone, or class IC agents are alternative therapies for orthodromic regular tachycardias. All of these drugs except adenosine are suitable for outpatient prophylaxis after termination of the tachycardia. Lidocaine is unlikely to have any effect on orthodromic WPW-related tachycardia, and magnesium is not well studied in this syndrome.

Symptomatic patients with an antidromic (wide QRS complex) regular tachycardia or any irregular tachycardia (irrespective of QRS duration) have a more serious prognosis because of the high risk of ventricular fibrillation, especially when the RR interval is less than 0.20 second. In these situations, AV nodal blocking drugs (calcium channel blocking agents, beta-adrenergic blocking agents, and digoxin) are contraindicated. These agents may create a faster ventricular response rate from unopposed conduction through the accessory pathway, which can lead to ventricular fibrillation. It is not clear whether adenosine, with its extremely short half-life, shares this risk, and adenosine has been used successfully in patients

with wide-complex, regular tachycardias (see Wide-Complex Tachycardias). When a wide-complex, irregular rhythm is present, however, adenosine is contraindicated, along with the other nodal-blocking agents. Irregularity can be difficult to detect at extremely fast rates and should be assumed present when there is doubt. A wide-complex irregular tachycardia at a ventricular rate of 250 beats per minute or greater is highly suggestive of atrial fibrillation and WPW syndrome.

Procanamide and amiodarone are the drugs of choice in antidromic or irregular WPW-related tachycardias. Electrical cardioversion is best any time the ventricular rate is 250 beats per minute or greater, drug therapy fails, or instability or clinical deterioration occurs. Lidocaine has limited utility in antidromic or irregular accessory pathway syndromes. It usually has little effect on conduction, although isolated reports of both decreased and enhanced conduction through the accessory pathway exist. For these reasons, lidocaine is not recommended for antidromic or irregular accessory pathway syndromes.

Patients who experience recurrence in the ED and those with underlying complicating diseases or symptoms (e.g., chest pain, congestive heart failure, electrolyte imbalance) should be admitted to the hospital or to an observation unit. Those without the aforementioned features in whom tachycardia is easily terminated can be discharged and referred as necessary for electrophysiologic studies to map the location of the pathway and potential radiofrequency ablation of the tract.

The Lown-Ganong-Levine syndrome is an uncommon accessory pathway syndrome associated with paroxysmal tachycardia, a short PR interval, and a normal QRS complex without a delta wave. Patients usually have a paroxysmal reentrant narrow-complex tachycardia. The treatment parallels that for the WPV syndrome.

**Wide-Complex Tachycardias**

Wide-complex tachycardia refers to dysrhythmias at a ventricular rate greater than 100 beats per minute and a QRS duration of 0.12 second or more. Wide-complex tachycardia can originate from foci in the ventricles (ventricular tachycardia) or above the ventricles (supraventricular tachycardia, SVT). Supraventricular foci can produce a wide-complex tachycardia if a conduction abnormality exists. The widened QRS seen in supraventricular rhythms occurs with a preexisting bundle branch block or an acquired bundle branch block (often related to fast or irregular heart rates and ischemia), or when conduction is through an accessory pathway. A focus below the level of the AV node results in ventricular tachycardia. The treatment of wide-complex tachycardia is based on the ability to distinguish ventricular tachycardia from SVT with abnormal conduction.

The approach to the differential diagnosis of a wide-complex tachycardia is based on systemic evaluation of evidence gained from a focused history, physical examination, and ECG tracing. The classic Wellens criteria38 (Table 77-7) use multiple, unordered clinical data points to help estimate the likelihood of a ventricular or supraventricular source. As an improvement, the Brugada and the Griffith criteria use the ECG principles incased in the Wellens approach, surrounded in a decision tree approach (Fig. 77-35). The Brugada approach39 uses four steps to identify ventricular tachycardia; if absent, an SVT is diagnosed. Griffith uses the opposite approach, identifying classic bundle block patterns to first identify SVT, then seeking AV dissociation to find ventricular tachycardia in the remainder. These two have similar performance in daily practice.38–41

No one criterion or system that helps distinguish a supraventricular from a ventricular source is infallible. A careful collection of multiple data points usually leads to the correct diagnosis. The treating physician should *always initially assume that any new-onset symptomatic wide-complex tachycardia is ventricular tachycardia until proved otherwise* (which often can be done by history, examination, and evaluating the ECG).

Patients with a history of a previous myocardial infarction are more likely to have ventricular tachycardia than SVT with abnormal conduction. This historical point, coupled with the onset of a dysrhythmia after the infarction, strongly suggests the diagnosis of ventricular tachycardia. Other features more frequently associated with ventricular tachycardia are an age of 50 years or older, known ischemic or structural heart disease, congestive heart failure, family history of early or sudden cardiac death, and a previous history of ventricular dysrhythmias. Conversely, younger patients (younger than 35 years) and those with a history of SVT are more likely to have a supraventricular source with abnormal conduction.

ASHD, arteriosclerotic heart disease; CABG, coronary artery bypass graft; LAD, left anterior descending artery.
During the physical examination, clues about the source of a wide-complex tachycardia can be gleaned. Evidence of AV dissociation (variation in the first heart sound or in the systolic blood pressure beat to beat or cannon jugular waves) suggests a ventricular origin. The absence of these findings, however, does not imply a supraventricular source. Slowing or termination of a wide-complex tachycardia in response to carotid sinus massage and other vagal maneuvers suggests a supraventricular source.

One common error in the differential diagnosis of wide-complex tachycardia is the belief that the blood pressure and level of consciousness can be used to distinguish ventricular tachycardia from SVT with abnormal conduction. Although ventricular tachycardia is more often associated with reduced cardiac output, hypotension, and a depressed sensorium, the absolute blood pressure and level of consciousness are not useful in discriminating ventricular tachycardia from SVT with abnormal conduction. Many patients with ventricular tachycardia tolerate the dysrhythmia well.

ECG clues to the origin of a wide-complex tachycardia can be distilled into a few simple rules (see Table 77-7 and Fig. 77-35). Again, evidence of AV dissociation strongly suggests a ventricular source for a wide-complex tachycardia. Retrograde conduction to the atria during ventricular tachycardia can occa-
sionally produce a consistent P′ wave after the QRS complex, creating the appearance of AV association (though the P waves should look abnormal). Another strong indicator that ventricular tachycardia is present is fusion beats, occurring when an atrial impulse reaches the AV node and infranodal conduction system at the same time as the ventricular impulse, creating a hybrid QRS complex. This hybrid fusion QRS complex is often intermediate in duration and structure between the narrow atrial impulse and the wide ventricular impulse.

The appearance of specific QRS patterns in the precordial leads, especially leads V1 and V6, can also help identify the origin of a wide-complex tachycardia (see Table 77-7). A QRS duration of greater than 0.14 second is more commonly associated with ventricular tachycardia, especially when coupled with a history of previous myocardial infarction. A bizarre QRS axis, manifested as an extreme left-axis deviation, also suggests ventricular tachycardia. Finally, a previous ECG tracing can be helpful; QRS complexes that are identical to those seen on an old ECG strongly suggest the same source. If the QRS morphology during a wide-complex tachycardia is the same as the morphology of sinus rhythm with bundle branch block, it is more likely that the wide-complex tachycardia is supraventricular with aberration rather than ventricular tachycardia.

The Brugada ECG criteria search for four pieces of evidence of ventricular tachycardia from among those listed previously; as soon as one is found, the diagnosis is made. The rhythm must be regular for these to be employed (chaos suggests atrial fibrillation with altered conduction). The sequential criteria are (see Fig. 77-35):

1. Absence of any RS complexes in the chest leads
2. RS duration (measured from beginning of R to deepest part of S wave) greater than 100 msec
3. AV dissociation (often present but overlooked may be best appreciated in inferior limb leads and V1–2)
4. Specific ventricular tachycardia morphologic criteria (Fig. 77-36)

Only when none of the criteria are present is a supraventricular etiology diagnosed. Although the original investigators found excellent sensitivity (98.7%) and specificity (96.5%) in detecting ventricular tachycardia, follow-up investigations have not duplicated this level of accuracy in ED patients (sensitivity 92–94%). Often, physicians either cannot complete or agree on the findings.

The Griffith criteria use a three-step approach seeking to identify aberrancy, first through classic RBBB or left bundle branch block (LBBB) morphologies in V1 and V6 to identify SVT, then seeking AV dissociation in the remainder to identify ventricular tachycardia (see Fig. 77-35). Like the Brugada approach, this has a real use sensitivity of 92%, although specificity may be less.

The regularity of the QRS complexes can be helpful in distinguishing ventricular tachycardia from SVT with abnormal conduction and in guiding treatment. Most episodes of ventricular tachycardia and SVT with abnormal conduction are completely or predominantly regular, although some irregularity can be seen with both. Nevertheless, a wide-complex tachycardia with an underlying chaotic rhythm (irregularly irregular) is strong evidence of atrial fibrillation with abnormal conduction. The conduction abnormality can result from a preexisting bundle branch block, an acquired bundle branch block (often in an RBBB appearance), or an accessory pathway syndrome. Atrial fibrillation with an accessory pathway syndrome, whether associated with a wide or narrow QRS complex, should not be treated with calcium channel blockers or digoxin because of the risk of precipitating ventricular fibrillation. Cardioversion, procainamide, or amiodarone should be used on accessory pathway syndromes.

Figure 77-36. The morphology associated with the fourth criterion in the Brugada system. A, In patients with a right bundle branch–appearing complex. B, In patients with a left bundle branch–appearing complex.
Unstable patients with a wide-complex tachycardia should be treated as if ventricular tachycardia is present. Patients with pulseless wide-complex tachycardia should be treated as outlined previously in the discussion of pulseless ventricular tachycardia and fibrillation. For unstable patients with a wide-complex tachycardia and a palpable pulse, cardioversion with 50 to 100 J initially (after sedation if time permits, biphasic discharge preferred but not mandatory) is recommended. If the initial countershock is unsuccessful, repeated attempts with increased doses in 50- to 100-J increments (up to a maximum of 360 J) should be administered. Although a biphasic, synchronized countershock is preferred, unsynchronized monophasic countershock of ventricular tachycardia is acceptable.

If the patient is “borderline unstable” (only one nonextreme symptom or sign is present) or if the patient is stable yet the source of the wide-complex tachycardia is unclear, treatment should proceed assuming that ventricular tachycardia is present. Pharmacologic agents such as amiodarone, lidocaine, or procainamide are best. Amiodarone is recommended as a first-line agent but may produce hypotension. The advantages of lidocaine are that it can be given rapidly and terminates most cases of ventricular tachycardia. Lidocaine is unlikely to have an appreciable effect on an SVT with abnormal conduction, but is also likely to cause no harm. Procainamide and amiodarone are preferable as the initial agent in patients with a wide-complex tachycardia of uncertain origin because both can convert both SVT (including those associated with accessory pathways) and ventricular tachycardia. Electrical cardioversion remains an option in stable patients if pharmacologic treatment fails. Because ventricular tachycardia does not usually respond to adenosine (only 5 to 10% of ventricular tachycardia cases terminate with this agent) and most SVTs are terminated or temporarily slowed, this agent can help differentiate the diagnosis of wide-complex tachycardia. Overall, this approach is relatively safe, although case reports of poorly defined hemodynamic collapse after adenosine administration in wide-complex tachycardia exist, tempering widespread enthusiasm for this approach.

Although calcium channel blockers have little direct effect on most forms of ventricular tachycardia, many patients with this rhythm experience immediate cardiovascular collapse from the vasodilatory effects of these drugs. When a supraventricular source for a wide-complex tachycardia is verified, the principles of treatment parallel those outlined for narrow-complex tachycardia. While agents such as adenosine and calcium channel blockers may sometimes seem suited to aid in the diagnosis of rhythm disturbances, it is important first to carefully evaluate the ECG in the context of a patient’s clinical and historical circumstances.

### Ventricular Tachycardia with Pulses

Ventricular tachycardia (QRS rate ≥100 beats/min) originates within or below the His bundle. On the ECG, a minimum of three consecutive wide QRS complex beats is necessary to diagnose ventricular tachycardia. Nonsustained refers to short episodes (≤30 seconds) that revert spontaneously, whereas sustained ventricular tachycardia refers to more prolonged episodes. Reentry mechanisms are the most common cause of ventricular tachycardia, although automatic and triggered mechanisms also occur. Ventricular tachycardia can be precipitated by any extrasystole, with PVCs the most common inciting stimulus. Extrasystole that occurs during ventricular repolarization (the R-on-T phenomenon) may carry a risk of precipitating ventricular tachycardia, although the magnitude of this risk is debated. Most patients with ventricular tachycardia have underlying heart disease or ischemia.

Several groups of ventricular tachycardia can be identified on the basis of the ECG pattern and history. Monomorphic ventricular tachycardia can occur in the presence or absence of ischemic heart disease and appears as morphologically consistent QRS complexes, usually in a regular pattern and at a rate of 150 to 200 beats per minute (Figs. 77-37 and 77-38). An irregular rhythm and a rate greater than 200 beats per minute or less than 150 beats per minute may be seen. Monomorphic ventricular tachycardia associated with chronic coronary artery disease is the single most common form of ventricular tachycardia.

Polymorphic ventricular tachycardia is manifested as QRS complexes that vary in structure or duration and is associated with more severe underlying disease (Figs. 77-39 and 77-40). Torsades de pointes is a specific form of polymorphic ventricular tachycardia. Bidirectional (or alternating) ventricular tachycardia occurs most frequently in digitalis intoxication and appears as a ventricular tachycardia with a QRS structure and axis that change periodically (see Fig. 77-39). During all forms of ventricular tachycardia, the main vectors of the ST segment and T wave are usually in an opposite direction from the terminal portion of the QRS complex. This phenomenon is termed a secondary repolarization abnormality.

Treatment of stable monomorphic ventricular tachycardia is based on correcting any underlying cause (especially electrolyte imbalance, hypoxemia or hypercapnia, and myocardial ischemia) and intervening pharmacologically to terminate the dysrhythmia. Amiodarone (3–5 mg/kg over minutes) or lidocaine (1.0–1.5 mg/kg bolus, up to 3 mg/kg maximum and followed by an infusion) are first-line choices, with up to 90% of episodes successfully terminated. Procainamide can be used as a second-line agent. Magnesium sulfate (2–4 g IV as a slow bolus) can augment or serve as a third-line agent in the treatment of ventricular tachycardia, especially in the setting of ischemia. Unstable patients or those refractory to drug therapy should be cardioverted with 50 to 100 J (again, biphasic synchronized preferred but monophasic acceptable), with escalating doses (up to 200 J biphasic or 360 J monophasic) as needed.

In the rare case of ventricular tachycardia caused solely by catecholamine excess, beta-adrenergic blockers may be useful in the primary treatment; otherwise, these agents are best suited for prophylaxis. Calcium channel blockers may prevent ventricular tachycardia associated with reperfusion but are not indicated for the treatment of ventricular tachycardia.

All patients with symptomatic ventricular tachycardia, new-onset ventricular tachycardia, or ventricular tachycardia requiring electrical therapy should be admitted. The rare patients eligible for discharge are those with chronic ventricular tachycardia who have no change in symptoms or evidence of acute ischemia. These patients should be released only after consultation with cardiologists familiar with their care and with close outpatient follow-up.

Many patients with ventricular tachycardia are candidates for an implanted defibrillator. The prognosis for patients with ventricular tachycardia depends on the symptoms and the presence of underlying heart disease. Those with structural heart disease and syncope have a poorer prognosis.

### Polymorphic Ventricular Tachycardia and Torsades de Pointes

Polymorphic ventricular tachycardia implies more severe underlying cardiac disease and is usually treated in the same way as monomorphic ventricular tachycardia. One specific form of polymorphic ventricular tachycardia requires recogni-
Torsades de pointes, literally translated as “twisting of the points,” is a paroxysmal form of ventricular tachycardia that meets the following clinical criteria (see Fig. 77-40):

1. Ventricular rate is greater than 200 beats per minute.
2. QRS structure displays an undulating axis, with the polarity of the complexes appearing to shift about the baseline.
3. Occurrences are often in short episodes of less than 90 seconds, although sustained runs can be seen.

Torsades often occurs in the setting of an existing prolonged QT interval during sinus rhythm, a reflection of abnormal ventricular repolarization. The normal range of QT duration must be corrected for age, sex, and heart rate. A QT interval of 500 msec or longer indicates an increased risk of torsades. Prolonged QT intervals can be congenital or acquired, with the latter being more common. Women have a greater risk of QT prolongation and torsades.

Acquired QT prolongation and torsades are often multifactorial, including interactions between drug therapy, myocardial...
Figure 77-38. Ventricular tachycardia. A, RS complexes are present in chest leads, but RS duration is greater than 100 msec. Although Brugada criteria indicate that no further analysis is necessary, atrioventricular dissociation is also evident and QRS morphology (R:S ratio <1 in lead V6) is consistent with ventricular tachycardia. B, Some RS complexes are present, RS duration is not greater than 100 msec, and atrioventricular dissociation is difficult to appreciate; morphologic criteria for ventricular tachycardia are fulfilled because S is notched in V1 and QR is present in V6. C, Diagnosis is based on morphologic criteria because S is notched in V1 and V2 and QS is present in V6. (Courtesy of Edward Curtis, MD.)

Dial ischemia, and electrolyte disturbances (hypokalemia and hypomagnesemia). Drugs (classes IA, IC, and III agents, plus many antibiotics, antifungals, antiemetics, antipsychotics, antiseizure medications, and a variety of other agents) can trigger prolonged QT intervals or torsades when new or in high concentrations, with abrupt infusion, or simply without warning. Delayed episodes (months after treatment is begun or altered) are often the result of an additive effect on ventricular repolarization, such as electrolyte imbalance, clearance issues (e.g., renal or liver failure), or addition of another drug implicated in this syndrome.

The majority of adult cases of torsades are acquired and pause dependent (Box 77-12). These episodes of torsades are precipitated by a slow heart rate. Treatment of intermittent torsades in stable patients is based on correcting any underlying metabolic or electrolyte abnormalities and increasing the heart rate to shorten ventricular repolarization. The latter can be done with overdrive pacing (external or transvenous) or beta-adrenergic infusion to achieve a ventricular rate of 100 to 120 beats per minute. Intravenous magnesium sulfate is also effective in treating paroxysmal torsades. Classes IA and IC agents are contraindicated because they may worsen the dys-

**BOX 77-12**  
**CLASSIFICATION AND CAUSES OF PROLONGED QT SYNDROMES THAT PRODUCE TORSADES**

#### Pause Dependent (Acquired)
- Drug induced: Class IA and IC antidysrhythmics; many phenothiazines/butyrophennones (notably haloperidol and droperidol), cyclic antidepressants, antibiotics (especially macrolides), organophosphates, antihistimines, antifungals, antiseizure and antiemetic agents
- Electrolyte abnormalities: hypokalemia, hypomagnesemia, hypocalcemia (rarely)
- Diet related: starvation, low protein
- Severe bradycardia or atrioventricular block
- Hypothyroidism
- Contrast injection
- Cerebrovascular accident (especially intraparenchymal)
- Myocardial ischemia

#### Adrenergic Dependent (Tachycardia Prompted)
- **Congenital**
  - Jervell and Lange-Nielsen syndrome (deafness, autosomal recessive)
  - Romano-Ward syndrome (normal hearing, autosomal dominant)
  - Sporadic (normal hearing, no familial tendency)
- **Acquired**
  - Cerebrovascular disease (especially subarachnoid hemorrhage)
  - Autonomic surgery: radical neck dissection, carotid endarterectomy, truncal vagotomy

Rhythmia by further prolonging repolarization. The class IB agents (including lidocaine and phenytoin) shorten repolarization, but their overall success rate is low in these cases. Amiodarone is an alternative therapy, although rarely it can precipitate this rhythm.

Patients who are unstable or in sustained torsades should be electrically cardioverted as with any ventricular tachycardia; synchronization will usually not be possible. In contrast, torsades de pointes associated with a congenital QT prolongation syndrome is much rarer, usually arising in childhood or early adulthood. This form is precipitated by catecholamine excess (e.g., exercise or medications) and termed tachycardia dependent. Patients may present with syncope after exertion. Similarly, torsades after neck surgery and cerebrovascular accidents may also be precipitated by catecholamine excess. Treatment of all forms of catecholamine-induced torsades is based on slowing the heart rate, usually with beta-adrenergic blockers. Other agents, such as magnesium sulfate, calcium channel blockers, amiodarone, or phenytoin, have varying effectiveness and are second-line therapies.
**Brugada’s Syndrome**

This syndrome (like prolonged QT syndromes) is associated with unpredictable ventricular dysrhythmias and syncope or sudden cardiac death, especially in those under 50 years old. Brugada’s syndrome results from an inherited disorder of sodium channels; it is most common in men and is most common in patients of Asian origin, although the syndrome has been reported in virtually every ethnic group. No structural heart disease accompanies this conductive disorder. It is appropriate to consider the possibility of Brugada’s syndrome when children, teenagers, or young adults present with unexplained syncope or symptomatic palpitations. In the ED, Brugada’s syndrome is diagnosed by its characteristic ECG pattern of elevation of the ST segment with a “saddle-back” or coved appearance in leads V1 to V3 (Fig. 77-41). Often, an RBBB pattern will coexist, and less commonly a first-degree AV block. The ST segment findings may be transient and variable, altering with time, drugs, or duress.

When Brugada’s syndrome is noted or suspected, admission for electrophysiology testing and implanted defibrillator insertion is the key to long-term care. Drug therapy is poorly studied, with only quinidine showing promise. Other class IA, IC, and III agents can help unmask the syndrome but are not therapeutic.

PERSPECTIVE

Electrical cardiac pacing for the management of bradyarrhythmias was first described in 1952, and permanent transvenous pacing devices were introduced into clinical practice in the early 1960s. The first devices for endocardial defibrillation were implanted in surviving victims of sudden cardiac death in 1980. Currently implanted electrical devices for the management of cardiac dysrhythmias have changed rapidly over the years with both increasing complexity and miniaturization. In 1991, it was estimated that 1 million patients in the United States had permanent pacemakers, and survey data from 1989 indicated that approximately 425 new pacemakers per million population were implanted annually in the United States. New indications for the use of permanent pacemakers in the management of congenital and acquired heart disease include cardiac resynchronization therapy for heart failure.

INDICATIONS FOR PERMANENT PACEMAKERS AND ANTIARRHYTHMIA DEVICES

Guidelines for the implantation of these devices have been developed by a joint task force of the American Heart Association and the American College of Cardiology (AHA/ACC) and are periodically updated. Using an evidence-based approach, recommendations are categorized as class I, II, or III. Class I includes conditions for which there is general agreement that a device should be implanted. A class II recommendation includes conditions for which these devices are frequently used but for which there is disagreement about their need or benefit. Class III is reserved for conditions for which there is general agreement that a device is not needed.

In the case of pacemaker therapy, additional factors are considered when selecting the mode of pacing and include, but are not limited to, overall health, lifestyle, and occupation of the patient. Class I indications for a permanent pacemaker or ICD are listed in Boxes 78-1 and 78-2. In general, pacing is recommended for patients with symptomatic heart block, symptomatic sinus bradycardia, and atrial fibrillation with a symptomatic bradycardia (low ventricular response rate) in the absence of medications that affect atrioventricular (AV) conduction. Controversial indications include pacing in patients with syncope, heart block, or fatigue in the presence of some conduction disease or bradycardia. The likelihood of a patient’s improvement after pacing can be assumed only if the symptoms can be closely correlated with inadequate rate.

Pacemaker Terminology

A letter code, initially established in 1974 and since revised as technology has advanced, standardized nomenclature for pacemakers. Table 78-1 includes an explanation of the five-letter code scheme and the standard abbreviations for each category. The first three code letters are used most commonly. Using this table, one should be able to understand the features of any pacing mode. For example, a VDD pacemaker is capable of pacing only the ventricle, sensing both atrial and ventricular intrinsic depolarization, and responding by dual inhibition of both atrial and ventricular pacing if intrinsic ventricular depolarization occurs; a paced ventricular beat is triggered in response to a sensed intrinsic atrial depolarization. The codes of a permanent pacemaker that are used most frequently and the indications, advantages, and disadvantages of each are listed in Table 78-2. Detailed algorithms for matching a patient with a pacemaker have been developed. The majority of permanent pacemakers are now dual chamber and often rate adaptive.

Pacemaker Components

All pacemaker systems have three basic components: the pulse generator, which houses the power source (battery); the electronic circuitry; and the lead system, which connects the pulse generator to the endocardium.

Nearly all implanted pacemakers are lithium powered. Lithium-powered pulse generators function normally for 4 to 10 or more years, depending on the pacemaker features, such as single versus dual chamber, pacing threshold, and rate adaptiveness. This long “battery life” and the fact that the output voltage of the lithium-iodine cell decreases gradually rather than abruptly, as occurred with the early mercury-zinc cell,
make sudden pulse generator failure an unlikely cause of pacemaker malfunction.

Permanent pacemakers have endocardial leads that are positioned in contact with the endocardium of the right ventricle and, in the case of a dual-chamber device, the right atrium, using a subclavian or cephalic vein approach for insertion. Occasionally, an epicardial lead may be implanted during open-heart surgery performed for another indication, such as prosthetic valve insertion or correction of a congenital cardiac defect. Pacemaker leads, like power sources, continue to undergo major technical improvements. Innovations include resilient plastic insulation surrounding the electrodes that reduces the chance of complete lead disruption or breakage (resulting in failure to pace or sense) or the chance of partial fracture (resulting in a “make or break” contact with intermittent failure to sense or pace). Despite these advances, problems with the electrical circuitry remain the most common cause of pacemaker malfunction. A lead capable of active fixation is more commonly used in patients with cardiomyopathies and right ventricular dilation complicated by tricuspid regurgitation.

### BOX 78-1
**Class I Indications for Permanent Pacing in Adults**

1. Third-degree and advanced second-degree AV block at any anatomic level associated with any of the following:
   - Symptomatic bradycardia (including heart failure) or ventricular dysrhythmia presumed to be due to AV block
   - Symptomatic bradycardia secondary to drugs required for dysrhythmia management or other medical condition
   - Documented periods of asystole lasting more than 3 seconds or an escape rate of less than 40 beats/minute or an escape rhythm originating below the AV node in an awake, asymptomatic patient in sinus rhythm
   - Awake, asymptomatic patients with atrial fibrillation and bradycardia a documented pause of 5 seconds or longer
   - After catheter ablation of the AV node
   - Postoperative AV block that is not expected to resolve
   - Neuromuscular disease with AV block (e.g., the muscular dystrophies)

2. Symptomatic bradycardia resulting from second-degree AV block regardless of type or site of block

3. Asymptomatic, persistent third-degree AV block with awake ventricular rate >40 bpm with cardiomegaly or LV dysfunction or if block is below AV node

4. Chronic bifascicular or trifascicular block with intermittent third-degree AV block or type II second-degree AV block

5. Second or third-degree AV block with exercise in the absence of myocardial ischemia

AV, atrioventricular.

### BOX 78-2
**Class I Indications for Implantable Cardioverter-Defibrillator Therapy**

1. Cardiac arrest resulting from VF or VT not caused by a transient or reversible event

2. Spontaneous sustained VT

3. Syncope of undetermined origin with clinically relevant, hemodynamically significant sustained VT or VF induced at electrophysiologic study when drug therapy is ineffective, not tolerated, or not preferred

4. Nonsustained VT with coronary artery disease, prior myocardial infarction, left ventricular dysfunction, and inducible VF or sustained VT at electrophysiologic study that is not suppressible by a class I antiarrhythmic drug

*In the triggered response mode, the pacemaker discharges or fires when it recognizes an intrinsic depolarization. As a result, pacemaker spikes occur during inscription of the QRS complex. Because this mode results in high-energy consumption and a shortened battery life and because the sensing response can be misinterpreted as pacemaker malfunction, this sensing mode is not used with modern pacemakers.

Pacemaker leads may be either bipolar or unipolar in configuration. A bipolar endocardial lead has both the negative (distal) and the positive (proximal) electrodes, separated by approximately 1 cm, within the heart. A unipolar lead has the negative electrode in contact with the endocardial surface, and the positive pole is the metallic casing of the pulse generator. Each lead system has potential advantages and disadvantages. The unipolar configuration is not compatible with ICD systems, is prone to oversensing of myopotentials and electromagnetic interference, but is of smaller diameter and less susceptible to fracture. The bipolar configuration is compatible with ICD systems but is larger and more prone to lead fractures. Oversensing, however, is rarely a problem. The selection of lead configuration usually depends on the experience and preference of the operator.

The Standard Electrocardiogram During Normal Cardiac Pacing

The modern pacemaker has two basic functions: to stimulate the heart electrically and to sense intrinsic cardiac electrical activity. Additional functions are available and noted in the pacemaker code system (see Table 78-1, letters 4 and 5). The pacemaker delivers an electrical stimulus to either the atrium or the ventricle if it does not recognize (sense) any intrinsic electrical activity from that chamber after a selected time interval. This interval is usually programmed at the time of implantation and can be changed noninvasively at a later time, if necessary, using a programming and “interrogating” device provided by the pacemaker manufacturer. If the pacemaker recognizes or senses an intrinsic atrial depolarization (P wave) or ventricular depolarization (QRS complex), it inhibits or resets its output to prevent competition with the underlying intrinsic rhythm. The stimulus intensity and sensing threshold (amplitude of electrical activity that is detected as being intrinsic) are typically set at the time of implantation but can also be reprogrammed later.

The two basic functions of a pacemaker can be easily recognized and confirmed on a standard 12-lead electrocardiogram (ECG) or rhythm strip. The normal function of a single-chamber VVI pacemaker is most easily recognized (Fig. 78-1). After a programmed interval is surpassed during which intrinsic ventricular activity does not occur, a pacer “spike” or stimulus artifact appears. The pacer spike is a narrow deflection that is usually less than 5 mm in amplitude with a bipolar lead configuration and usually 20 mm or more in amplitude with a unipolar lead. A wide QRS complex appears immediately after the stimulus artifact. Depolarization begins in the right ventricular apex, and the spread of excitation does not follow normal conduction pathways. Characteristically, a left bundle branch block conduction pattern is seen. A right bundle branch pattern is abnormal and suggests lead displacement. In VVI pacing, the paced QRS complexes are independent of intrinsic atrial depolarization if present (AV dissociation).

The recognition of normal dual-chamber pacing is more complex due to the interactive sensing and pacing of the right atrium and ventricle (Fig. 78-2). Pacing intervals are preprogrammed, may be changed noninvasively at a later time, and are generally specific to the patient’s needs. Pacing rates and delay intervals typically vary from patient to patient. Dual-chamber devices are typically used in patients with non-fibrillating atria coupled with intact AV conduction. A normal-appearing QRS complex may follow an intrinsic “p” wave due to normal sinoatrial node discharge if the intrinsic atrial depolarization is conducted to the ventricles. The intrinsic p wave and QRS complex inhibit the atrial and ventricular circuitry. A normal QRS complex follows a paced p wave if the paced atrial beat is conducted through the AV node and the programmed AV delay period is not exceeded. If it is not conducted to the ventricles (AV delay period exceeded), the pacemaker stimulates the ventricle, resulting in a paced p wave and a wide, paced QRS complex with left bundle branch block configuration.

Recognition of the interactivity of the paced chambers is important. A paced p wave may be mistaken for failure to sense or pace, and malfunction may be diagnosed when it is not present (pseudomalfunction). In addition, if the programmed rate of the pacemaker approximates the patient’s intrinsic heart rate, fusion of paced and native beats may occur and represents another common type of pseudomalfunction (Fig. 78-3).

Complications of Implantation

Infection

Pacemaker implantation is a surgical procedure and, like all surgery, carries a risk of infection, and the presence of a foreign body enhances this risk. The incidence of infection is small—approximately 2% for wound and subcutaneous pacemaker “pocket” infection and approximately 1% for bacteremia with sepsis. The presence of a foreign body complicates management, and few cases of bacteremia that develop after implantation can be managed with antibiotics alone. In most instances, reimplantation and replacement of the lead system are necessary.

Pain and local inflammation at the site of the pacemaker are the first manifestations of a wound infection, cellulitis, or pocket infection. Approximately 20 to 25% of patients with a local infection have positive blood cultures. Bacteremia may occur in the absence of a focal infection and may arise with the typical manifestations of the systemic inflammatory response.
response syndrome or sepsis. A hematoma of the pacemaker pocket may mimic a wound or pocket infection. Needle aspiration of the pocket should only be done under fluoroscopy because the needle may cut the insulation surrounding the pulse generator or the portion of the pacemaker lead that lies within the pacemaker pocket.

When a local infection or bacteremia is suspected, blood cultures should be obtained and intravenous antibiotic therapy initiated. *Staphylococcus aureus* and *S. epidermidis* are isolated in approximately 60 to 70% of cases. Empirical antibiotic therapy should include vancomycin pending culture and sensitivity data. If blood cultures are positive, the pulse generator and pacemaker lead are usually removed, temporary transvenous pacing is performed, and intravenous antibiotic therapy is continued for 4 to 6 weeks. The permanent pacemaker and lead are subsequently reimplanted.17

**Thrombophlebitis**

The incidence of venous obstruction associated with permanent transvenous pacemakers ranges from 30 to 50%, with approximately one third of patients having complete venous occlusion.19 Thrombosis of varying degrees can involve the axillary, subclavian, and innominate veins or the superior vena cava (SVC). The site of insertion does not appear to affect the incidence of this complication. Chronic thrombosis of the veins of the upper arm is common and usually asymptomatic owing to extensive venous collateral circulation.

Because of extensive collateralization, only approximately 0.5 to 3.5% of patients develop symptoms usually indicative of acute thrombosis. These patients typically present with edema, pain, and venous engorgement of the arm ipsilateral to the site of lead insertion. Although rare, SVC syndrome resulting from pacemaker lead-induced thrombosis is reported. The symptoms and signs of lead-induced SVC syndrome are identical to those described in patients with SVC syndrome and malignancy. Whether pulmonary embolism is associated with pacemaker therapy and thrombosis is controversial.

Although symptoms might suggest thrombosis, definitive diagnosis of acute thrombosis usually requires duplex sonography of the jugular venous system, conventional venography, or contrast-enhanced computed tomography. The symptoms

---

**Figure 78-2.** Normal DDD pacemaker (12-lead electrocardiogram). Each QRS complex is preceded by two pacemaker spikes. The first spike results in atrial depolarization, and the second produces a wide QRS complex. The QRS complex is conducted with a left bundle branch morphology, which is expected with endocardial pacing at the right ventricular apex.

**Figure 78-3.** VVI pacemaker with fusion beats (pseudomalfuction). This VVI pacemaker was implanted in a patient with atrial fibrillation and intermittent symptomatic complete heart block. In the lead II rhythm strip, the first five QRS complexes are normal in morphology and irregular, as would be expected in atrial fibrillation. The next two QRS complexes are wide and preceded by a pacemaker spike. This represents normal sensing and pacing. The 8th QRS complex is narrow but preceded by a pacemaker spike. The spikes occur at a fixed and regular interval. In this instance, spontaneous ventricular depolarization had begun at approximately the time the pacemaker discharged. The 12th QRS complex in the sequence represents a fusion beat. Within the QRS complex of the 13th beat, a pacemaker spike is visible. Again, this represents nearly simultaneous conduction of a supraventricular beat and pacemaker electrical discharge. At first glance, this may appear to be failure to sense; however, the pacemaker is functioning normally and competing with the underlying rhythm.
Causes of Pacemaker Malfunction

- Failure to capture
  - Lead disconnection, break, or displacement
  - Exit block
  - Battery depletion
- Undersensing
  - Lead displacement
  - Inadequate endocardial lead contact
  - Low-voltage intracardiac p waves and QRS complexes
  - Lead fracture
- Oversensing
  - Sensing extracardiac signals: myopotentials
  - T wave sensing
- Inappropriate rate
  - Battery depletion
  - Ventriculoatrial conduction with pacemaker-mediated tachycardia
  - 1:1 response to atrial dysrhythmias

The “Pacemaker Syndrome”

After pacemaker implantation, a patient may present with new complaints or report a worsening of the symptoms that prompted evaluation and eventual pacemaker therapy. Such complaints often include syncope or near-syncope, orthostatic dizziness, fatigue, exercise intolerance, weakness, lethargy, chest fullness or pain, cough, uncomfortable pulsations in the neck or abdomen, right upper quadrant pain, and other nonspecific symptoms.

These symptoms are termed the pacemaker syndrome. The etiology of this syndrome is the loss of AV synchrony and the presence of ventriculoatrial conduction, and it is most commonly encountered in the setting of VVI pacing. It is also described with the DDI mode. With VVI pacing, the ventricle is electrically stimulated and depolarized, resulting in ventricular systole. If sinus node function is intact, the atria can be depolarized by a sinus impulse and contract when the tricuspid and mitral valves are closed. This contractile asynchrony results in an increase in jugular and pulmonary venous pressures and may produce symptoms of congestive heart failure.

Atrial distention can result in reflex vasodepressor effects mediated by the central nervous system. Elevated levels of B-type natriuretic peptide and diuresis are considered markers for the syndrome in its more severe form. If the contribution of atrial contraction to late diastolic ventricular filling is important in maintaining an adequate cardiac output, basal and orthostatic hypotension may occur. DDI pacing in a patient with AV block may result in this syndrome if the sinus node discharge rate exceeds the programmed rate of the pacemaker.

Approximately 20% of patients report symptoms suggesting the pacemaker syndrome after pacemaker insertion. In most instances, symptoms are mild and patients adapt to them. In approximately one third of these patients, symptoms are severe. Treatment usually requires replacing a VVI pacemaker with a dual-chamber pacemaker or lowering the pacing rate of the VVI unit. If symptoms occur in a patient paced in the DDI mode, optimizing the timing of atrial and ventricular pacing is usually required. Patients appear to prefer dual-chamber pacing to the VVI modality.

Although the pacemaker syndrome may be suspected in the emergency department in the patient with suggestive symptoms soon after pacemaker implantation, consultation with a cardiologist for interrogation of the pacemaker is recommended. The same symptoms may be observed in patients with true pacemaker malfunction, which may necessitate pacemaker reprogramming or replacement of the pulse generator or pacemaker lead.

Pacemaker Malfunction

The term pacemaker malfunction refers specifically to problems with the circuitry or power source of the pulse generator, the pacemaker lead (most commonly displacement or fracture), or the interface between the pacing electrode and the myocardium (pacing or sensing threshold). In addition, environmental factors such as extracardiac or extracorporeal electrical signals may interfere with normal pacemaker function. Using the standard ECG, pacemaker malfunction can be separated into three broad categories: (1) failure to capture (no pacemaker spikes or spikes not followed by an atrial or ventricular complex), (2) inappropriate sensing (oversensing or undersensing spikes occur prematurely or do not occur even though the programmed interval is exceeded), or (3) inappropriate pacemaker rate. Symptomatic pacemaker malfunction after implantation occurs in less than 5% of patients and is rarely immediately life-threatening. Malfunction is most commonly due to inappropriate sensing, followed by failure to capture. Typical presentations and etiologies of pacemaker malfunction are listed in Box 78-3.

The emergency physician suspects pacemaker malfunction, knowledge of the pacing modalities (see Table 78-1) and what is normal for a given pacing modality are critical when reviewing the ECG. Fortunately, patients are provided with important identifying information, usually in the form of a wallet card, after pacemaker implantation. The most important information for the emergency physician is provided in the five-letter code. If this information is not available, a standard posteroanterior and a lateral chest radiograph can provide critical information. A single lead in the apex of the right ventricle indicates a VVI pacemaker. With VVI pacing, only one stimulus artifact or spike is seen with each stimulated ventricular depolarization (see Fig. 78-1). If sinus node activity is present, the paced QRS complex is dissociated from the intrinsic p waves. If separate leads are identified in the right atrium and right ventricle, the pacing modality is most often DDD or DVI, and paced p waves and QRS complexes (two spikes for each QRS complex) are seen (see Fig. 78-2). Although DDD and DVI units are capable of pacing both the right atrium and the right ventricle, only one spike may be seen (Fig. 78-4). Failure to identify two spikes with a DDD or DVI unit can represent normal pacemaker function.

A magnet placed externally over the pulse generator is frequently used in the assessment of pacemaker function. Magnet application causes closure of a reed switch within the pacemaker circuitry, converting the pacemaker to an asynchronous or fixed-rate pacing mode, and the pacemaker is no longer inhibited by the patient’s intrinsic electrical activity. The technique is most commonly used when the patient’s intrinsic heart rate exceeds the pacemaker’s set rate and pacemaker function is inhibited. Magnet application then allows pacing to occur, despite the patient’s native cardiac activity, and pacing rate and the presence of capture can be determined. Magnets are made by each manufacturer, but any cardiac pacemaker magnet will typically activate the reed switch within any of the devices.
Failure to Capture

Failure to capture may range from the complete absence of pacemaker spikes to spikes not followed by a stimulus-induced complex (Fig. 78-5). A complete absence of pacemaker spikes may result from battery depletion, fracture of the pacemaker lead, or disconnection of the lead from the pulse generator unit.

Current lithium-iodine batteries are not subject to sudden power failure, and they display typical end-of-life functional changes over a period of months to a year before complete depletion. Usually, the first sign of voltage depletion is a decrease in the programmed pacing rate. This change is gradual and should be detected during the regular follow-up evaluations that pacemaker patients receive. When voltage output falls to a critical level, stimulus strength falls below the required threshold and failure to capture or intermittent failure to capture may be observed late in battery life. As a result, urgent or emergent battery replacement is rare.

Failure to capture, which may be complete or intermittent, is most commonly a lead problem. Lead displacement is the most common cause and is most likely to occur within the first month of pacemaker insertion. The chest radiograph may demonstrate the tip of the pacing catheter displaced from the right ventricular apex. The catheter tip is commonly found in the pulmonary outflow tract, where it may have intermittent contact with endocardium, resulting in intermittent failure to pace and sense. The atrial leads of dual-chamber devices are commonly displaced into the body of the right atrium, resulting in loss of contact between the pacing lead and the atrial endocardium.

Lead fracture, which is uncommon with the current polyurethane lead coating, produces an insulation break, resulting in failure to capture as a result of current leakage. It can be detected as a change in pacing threshold. Lead fractures occur at predictable locations, usually at the site of attachment to the pulse generator or at abrupt angulations that serve as stress points. Inadequate contact of the lead with the pulse generator...
can mimic a lead fracture. Occasionally, when a lead fracture is complete or nearly complete, a break in the catheter or its insulation can be detected on an overpenetrated posteroanterior chest radiograph. Loss of lead–pulse generator contact can be detected on the chest radiograph with close inspection of the pulse generator.

Exit block (the failure of an adequate stimulus to depolarize the paced chamber) can also result in failure to pace. Exit block should be considered when the preprogrammed pacing stimulus output fails to result in capture in the presence of a normally functioning pulse generator and an intact lead system. This problem is most commonly due to changes in the endocardium in contact with the pacing system. Etiologies include ischemia or infarction of the endocardium in contact with the electrodes; systemic hyperkalemia; and the use of class III antiarrhythmic drugs, such as amiodarone, which affect ventricular depolarization. Although other drugs are reported to alter pacemaker threshold, the effect is small and is rarely clinically important.21 At the time of pacemaker insertion, stimulus strength, defined as the amplitude and duration of the electrical output, is always set substantially above the minimum required to result in an artificial electrical depolarization.

Inappropriate Sensing

For a pacemaker to function in a noncompetitive mode, it must be capable of sensing the intrinsic or “native” electrical activity of the heart. The electrical activity that is sensed is determined by the pacing modality (see Table 78-1). Sensing parameters are determined at the time of pacemaker insertion on the basis of the signal size of the intracardiac ECG and can be changed or fine-tuned externally at a later time if needed.

Undersensing

Failure to sense may be complete or intermittent. It may result from a change in the sensing parameters selected at the time of insertion. This is most commonly encountered after acute right ventricular infarction or during the progressive fibrosis that accompanies many cardiomyopathies, causing intracardiac signals to decrease in amplitude. Lead displacement, fracture, and poor contact with the endocardium may also cause undersensing.

Undersensing is typically recognized electrocardiographically as the appearance of pacemaker spikes occurring earlier than the programmed rate. The spike may or may not be followed by a paced complex, depending on when it occurs during the cardiac refractory period (Fig. 78-6). Failure of a stimulus spike to produce a complex when it occurs during the atrial or ventricular refractory period should not be interpreted as failure to pace.

Oversensing

In rare instances, the pacemaker may detect electrical activity that is not of cardiac origin. The result may be intermittent, irregular pacing or an apparent complete absence of pacemaker function. Myopotentials produced by the pectoralis muscle (Fig. 78-7) and extracorporeal electrical signals are frequently oversensed when a unipolar lead system is used. T waves following an intrinsic ventricular depolarization are the most common oversensed cardiac signals. Common medical sources of electrical interference include electrocautery, which can cause temporary pacemaker inhibition, and magnetic resonance imaging, which can alter pacemaker circuitry and result in fixed-rate or asynchronous pacing. Electromagnetic interference resulting from close proximity to a microwave oven should not cause pacemaker problems with currently implanted pacemaker units. Interference can be caused by the use of a digital cellular phone.21,22 These devices may cause pacemaker inhibition, inappropriate ventricular tracking, or asynchronous pacing. Malfunction is most commonly seen when the phone is within 10 cm of the pulse generator and often occurs when the phone is applied to the ear ipsilateral to the site of the pacemaker pocket.

![Figure 78-6](image1.png)

**Figure 78-6.** Failure to sense or undersensing (lead II). Pacemaker spikes are evident during inscription of the ST segment on this rhythm strip. These spikes do not produce QRS complexes because they occur during the ventricular refractory period of the preceding spontaneous QRS complex. The third QRS complex on the strip is a paced QRS complex. The device is capable of capture but is undersensing the spontaneous rhythm.

![Figure 78-7](image2.png)

**Figure 78-7.** Oversensing (lead II). This VVI unipolar lead pacemaker is oversensing myopotentials produced by contraction of the pectoralis major. Myopotentials result in the undulating and irregular baseline seen in the middle of the strip. After muscular contraction ceases, normal pacing resumes (last four complexes on the strip).
Inappropriate Pacemaker Rate

A pacing rate below the programmed rate is a typical finding in pulse generator depletion and does not occur abruptly with lithium-iodine batteries. An extreme increase in pacing rate, the so-called runaway pacemaker, is rarely, if ever, encountered with current pacemaker technology and circuitry in which upper rate limits are set (typically <140/min). An “endless loop” tachycardia may develop during dual-chamber pacing when ventriculoatrial conduction occurs and the resulting retrograde atrial depolarization results in a stimulated or paced ventricular depolarization. If atrial flutter develops during dual-chamber pacing, flutter waves may be sensed and tracked, resulting in a rapid, paced ventricular rate. In both instances, the ventricular rate does not exceed its set upper limit. Patients with such rhythms may complain only of palpitations or symptoms of hemodynamic compromise. When such rhythms are detected, magnet application usually converts the pacemaker to a fixed rate in a competitive mode and terminates the tachyarrhythmia.

Management

History

The patient should be asked for the pacemaker identification card. The information on the card explains why a pacemaker was placed and the pacing modality used.

Most patients with pacemaker malfunction present with symptoms reminiscent of those that prompted pacemaker therapy: syncope, near-syncope, orthostatic dizziness, light-headedness, dyspnea, or palpitations.

The majority of pacemaker complications and most instances of pacemaker malfunction occur within the first few weeks or months of pacemaker implantation. After wound healing, palpation of the pulse generator site should not elicit tenderness. A wound infection or pocket infection typically arises with localized pain. Bacteremia secondary to infection of the pacing catheter, however, may arise only with fever and without other manifestations of the systemic inflammatory response syndrome. Pain in the arm ipsilateral to the site of insertion should suggest acute thrombophlebitis.

Patients who develop the pacemaker syndrome secondary to the loss of AV synchrony may present with nonspecific complaints of easy fatigability, generalized weakness, dyspnea, or an uncomfortable fluttering or “pounding” sensation in the neck or abdomen. Syncope or near-syncope may also occur, but these complaints should prompt an evaluation for true pacemaker malfunction. The pacemaker syndrome should be a diagnosis of exclusion.

Physical Examination

A pacemaker infection should be suspected in the presence of fever, even if another potential source of infection can be identified. Extremely low (<60) beats per minute or high pulse rates (>100 beats per minute in the resting patient) are suggestive of altered pacing parameters (battery depletion or pacemaker-mediated tachycardias). Hypotension may be present in either instance. Cannon “a” waves on inspection of the jugular venous pulse wave indicate AV asynchrony. Auscultation of lungs may reveal bibasilar rales if congestive heart failure is present.

During pacing, the first heart sound may vary in intensity as a result of AV dissociation (VVI mode), and the second heart sound may be paradoxically split when ventricular pacing occurs (the right ventricle is activated first). A pericardial friction rub may also be heard if the tip of the pacing catheter has perforated the wall of the right ventricle. Perforation, however, usually occurs at the time of pacemaker implantation and is usually recognized at that time. Although the pacing catheter traverses the tricuspid valve, tricuspid regurgitation is rarely heard unless there is myocardial disease such as right ventricular dilatation that is common in the cardiomyopathies. Pedal edema may be present and is important if it is a new symptom or if chronic edema has recently worsened.

Chest Radiograph

A chest radiograph should be obtained to define pacing catheter tip position and to determine the number of pacing leads, unless this information is available from another source. A ventricular pacing catheter tip in the right ventricular outflow tract or an atrial catheter tip in the SVC or right ventricle is always abnormal. The pulse generator site should also be examined on the radiograph. Occasionally, disconnection of the lead from the pulse generator may be observed. In some cases, this is due to the patient’s manipulation of the pulse generator (“twiddler’s syndrome”).

12-Lead Electrocardiogram

A standard ECG and a long rhythm strip should be obtained in all patients. With bipolar pacing systems, the stimulus artifact may be extremely small and difficult to recognize in some leads (see Fig. 78-4). Inspection of the rhythm strip may reveal failure to sense or pace, a low pacing rate, or an abnormally rapid rhythm, suggesting a pacemaker-mediated tachycardia.

Disposition of the Emergency Department

Patient with a Pacemaker

As a result of the current design of modern pacemakers and the frequent follow-up evaluation of patients with pacemakers, life-threatening emergencies resulting from pacemaker malfunction requiring immediate emergency department intervention are rare. Most instances of malfunction are subtle and difficult to recognize without interrogation of the pacemaker using manufacturer-specific devices by someone skilled in the technique. In all instances of suspected pacemaker malfunction, the patient’s cardiologist should be consulted.

Advanced Cardiac Life Support Interventions

Electrical defibrillation at recommended shock strengths (200, 300, and 360 J) can be safely performed in the patient with a pacemaker. If the sternal paddle is placed adjacent to the sternum, it is at a safe distance (≥20 cm) from the pulse generator. Alternatively, defibrillation electrodes can be placed in an anteroposterior configuration. A cardiologist should ensure that the pacing parameters of the unit have not been altered if the resuscitation is successful. A chest radiograph should also be obtained after resuscitation to ensure that the pacing catheter was not displaced during chest compression, although this is an extremely uncommon occurrence.

Immediate return of pacing (capture) may not occur after defibrillation; this is commonly the result of global myocardial ischemia and increased pacing threshold and is not an indication of pacemaker malfunction. Temporary transcutaneous pacing may be needed if the pacemaker cannot be reprogrammed. Transcutaneous pacing can also be safely used because the anterior and posterior pacing electrodes, if properly positioned, are distant from the pulse generator. Attempt-
ing temporary transvenous pacing is usually not necessary and is unlikely to be successful, especially if undertaken without fluoroscopic guidance. Chronic venous thrombosis, which is common and most often asymptomatic after pacemaker insertion, may preclude temporary catheter insertion through the neck veins. Insertion through the femoral vein is also difficult because the permanently implanted catheter may prevent entry into the right ventricle. Blind insertion may also dislodge the permanent catheter.

**IMPLANTABLE CARDIOVERTER-DEFIBRILLATORS**

The ICD was first used clinically in 1980. Technical refinements in this modality for treating ventricular dysrhythmias have progressed even more rapidly than refinements in the less complex standard pacemaker. A surge in the use of ICDs reflects improved survival with ICDs versus antiarrhythmic therapy in patients at risk for sudden death resulting from ventricular dysrhythmias. Generally accepted indications for ICD implantation are noted in Box 78-2. Many patients still require drug therapy after ICD implantation to suppress ventricular dysrhythmias, minimize the frequency of ICD shocks, improve patients’ tolerance, and decrease energy use, which prolongs ICD life.

**Terminology and Components**

The majority of ICDs are now placed percutaneously in a manner similar to that of the standard pacemaker. A transvenous electrode system has largely replaced epicardial lead placement, which required thoracotomy. An epicardial defibrillation lead may occasionally be placed during coronary artery bypass surgery or in a few patients who cannot be defibrillated using existing transvenous electrode systems.

The typical modern ICD consists of components similar to those in the standard permanent pacemaker—namely, a power source, electronic circuitry, and lead system. In addition, the standard ICD has a high-voltage capacitor and complex microprocessor memory. The power source is lithium chemistry based with a battery life of 5 to 10 years. The longevity is largely determined by the frequency of shocks. All ICDs are also ventricular pacemakers, providing pacing for bradyarrhythmias.

The right ventricular lead is used for sensing and pacing, and shocks are typically delivered between a coil in the right ventricular lead and the pulse generator. If dual-chamber pacing is required, a second lead is placed in contact with the endocardium of the right atrium. A biphasic waveform is currently the preferred waveform for internal defibrillation. The shape and characteristics of the shock waveform vary among manufacturers. The biphasic waveform is more effective at lower energies than earlier monophasic waveforms and allows a smaller capacitor to be used, thereby reducing the size and increasing the comfort of the ICD unit.

The diagnostic and treatment functions of the ICD are determined at the time of implantation. In most instances, the cardioversion and defibrillation thresholds are determined at the time of ICD insertion by inducing ventricular tachycardia (VT) and fibrillation and adjusting the shock strength at a level above the minimum required to terminate the induced rhythm. Optimally, the required shock strength for defibrillation is less than half the maximum output (approximately 30 J) of the device. VT is typically managed using either low-energy shocks or programmed pacing that interrupts the VT reentrant circuit. Programmed pacing is less likely to have proarrhythmic effects and requires less energy, thereby extending battery life. In the setting of ventricular fibrillation (VF), ICDs are capable of delivering up to five additional discharges if the first shock fails.

The patient with an ICD should have close follow-up monitoring by a cardiologist familiar with ICD programming. This allows the cardiologist to determine the frequency of ICD activation (programmed antitachycardia pacing or shocks) and to confirm the programmed functions of the device. The majority of patients with ICDs have underlying heart disease, most commonly extensive atherosclerotic coronary artery disease, that is complicated by a low ejection fraction and congestive heart failure. The patient’s medications and metabolic status, such as electrolyte disorders that accompany diuretic usage, may also affect ICD function.

**Complications of Implantation**

Complications of ICD implantation are nearly identical in type and frequency to those of permanent pacemaker implantation. They include infection of the wound, the subcutaneous pouch fashioned for the device, and the lead system as well as acute thrombophlebitis and chronic thrombosis of the veins traversed for lead insertion. Management of these complications is similar to that for patients with permanent pacemakers.

**Malfunction**

Patients with ICD malfunction usually present to the emergency department with a limited number of specific symptoms (Box 78-4).

In contrast to patients with a permanent pacemaker, ICD patients are aware of when the ICD discharges to terminate VT or VF. The most common complaint of ICD patients is the occurrence of frequent shocks (i.e., occurring at a rate greater than they are accustomed to). Increasing shock rate may be appropriate and not indicative of ICD malfunction if the patient is experiencing an increase in the frequency of VT or VF episodes. An increase in the frequency of episodes may occur in the setting of hypokalemia, hypomagnesemia, ischemia (with or without infarction) related to underlying coronary artery disease, or the proarrhythmic effect of drugs

---

**BOX 78-4**

**CAUSES OF IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR MALFUNCTION**

- Increase or abrupt change in shock frequency
  - Increased frequency of VF or VT (consider ischemia, electrolyte disorder, or drug effect)
  - Displacement or break in ventricular lead
  - Recurrent nonsustained VT
  - Sensing and shock of supraventricular tachyarrhythmias
  - Oversensing of T waves
  - Sensing noncardiac signals
- Syncope, near-syncope, dizziness
  - Recurrent VT with low shock strength (lead problem, change in defibrillation threshold)
  - Hemodynamically significant supraventricular tachyarrhythmias
  - Inadequate backup pacing for bradyarrhythmias (spontaneous or drug induced)
- Cardiac arrest
  - Assume malfunction, but probably due to VF that failed to respond to programmed shock parameters

VF, ventricular fibrillation; VT, ventricular tachycardia.
An ICD does not prevent sudden death in all patients at risk, and a patient with an ICD may present in cardiac arrest (2% annual incidence in implanted patients). Cardiac arrest is not necessarily an indication of ICD malfunction. Appropriate repeated shocks may have been delivered but were ineffective. Alternatively, the ICD may not have sensed VF or the ventricular ectopic activity that typically precedes VF. Resuscitation efforts in the patient with an ICD should be undertaken in accordance with current recommendations. Transthoracic defibrillation can be performed in the standard manner with a monophasic or biphasic defibrillator if VF is the arrest rhythm. The sternal electrode or paddle should be placed in a parasternal location approximately 10 cm from the ICD subcutaneous pouch if the device has been implanted in the right deltopectoral area. If it has been implanted in the left deltopectoral region, this recommended safety distance is usually exceeded.

If the ICD discharges during manual chest compressions, the rescuer may feel a weak shock. There have been no reports of injury to rescuers from such discharges during resuscitation efforts. The device can be deactivated with magnetic application during resuscitation efforts. Deactivation is probably more important in the immediate postresuscitation period because recurrent ventricular dysrhythmias are common at this time following prolonged global myocardial ischemia during the arrest period, reperfusion, and the hyperadrenergic state worsened by the use of intravenous epinephrine during resuscitation. ICD malfunction should be assumed and these postresuscitation rhythms treated with standard pharmacologic agents (lidocaine and amiodarone). Although class I antidysrhythmic agents may raise the defibrillation threshold of the ICD, their impact on the defibrillation threshold during transthoracic countershock is clinically inconsequential due to the high shock strengths that are used.

**Disposition of the Emergency Department Patient with an Implantable Cardioverter-Defibrillator**

As a result of the difficulty in documenting or excluding ICD function or malfunction in the patient with transient symptoms, the device should be interrogated by the patient’s cardiologist to guide further evaluation and therapy. In cases in which the patient reports a single ICD shock, an assessment for acute cardiac ischemia, worsening of chronic congestive heart failure, symptoms of new-onset heart failure, and electrolyte abnormalities should be performed. In the absence of a change in clinical status, such patients can be discharged in consultation with the managing or consulting cardiologist after assuring timely follow-up. For patients reporting multiple shocks, immediate consultation is required along with admission to a monitored setting for extended telemetric observation. If frequent ventricular ectopy is noted, intravenous amiodarone should be given. ICD interrogation allows assessment of ICD function and preceding dysrhythmia episodes. Reprogramming may be necessary. If a lead problem is detected, reimplantation is required. A magnet can be placed over the ICD to inactivate the defibrillator. This should be done only if the emergency physician is confident that the ICD is delivering inappropriate shocks, such as a supraventricular tachycardia.

**Biventricular Pacing**

Biventricular pacing, also known as cardiac resynchronization therapy, is a new therapy for patients with left-sided heart failure and ventricular dyssynchrony. It is beneficial for patients with NYHA class 3 or 4 heart failure despite optimal medical therapy, a left ventricular ejection fraction of 35% or less, and sinus rhythm with QRS duration of 120 msec or greater. Left bundle branch block causes an altered sequence of depolarization of the left ventricle such that the interventricular septum contracts before the left ventricular free wall, leading to inefficient mechanical pumping. Biventricular pacing “resynchronizes” the ventricles by simultaneously pacing the left and right ventricles, eliminating the delay in left ventricular free wall contraction, and improving systolic function.
The complications and malfunctions inherent with conventional cardiac pacing are also observed with biventricular pacing. In addition, biventricular pacing has unique complications related to placement of the left ventricular pacing lead through the coronary sinus. In large clinical trials, coronary sinus dissection occurred in 0.3 to 4.0% of patients. Cardiac tamponade due to perforation of the coronary venous system is seen in less than 1% of patients. Dislodgement of the left ventricular electrode with resultant loss of pacing occurs as an early complication in approximately 10% of patients. Patients with malfunction of a biventricular pacing system frequently present with complaints of palpations or acute decompensation of chronic heart failure.

**Left Ventricular Assist Devices**

Mechanical ventricular assistance devices have been used as a “bridge” to transplantation since the 1960s.28 These implanted devices replace or support the pump function of the left ventricle and were originally bulky and mechanically complex due to the pulsatile nature of the pump mechanisms. This usually resulted in extended in-hospital care while the patient awaited cardiac transplantation. Newer devices, such as the Jarvik 2000 and HeartMate II, are continuous flow pumps that are portable and powered with a comparatively smaller battery pack. Implantation is associated with fewer infectious complications and lower immediate postoperative mortality, and survival for more than 1 year is increasingly common. The greatest mortality is noted within the first 30 days after implantation and during hospitalization. Left ventricular assistance devices (LVADs) are commonly used as “destination” therapy in patients who do not qualify for cardiac transplantation.29

Patients with an LVAD typically require care at cardiac transplant centers. As technology progresses, emergency physicians not based at a transplant center may encounter a patient with an LVAD. The more common complications with this device include infection and embolic stroke. Device failure usually results in severe congestive heart failure. If necessary, dopamine, dobutamine, or a combination of these drugs may be given to treat congestive heart failure symptoms while the patient awaits transfer. LVAD patients in cardiac arrest should be provided standard advanced cardiac life support.

---

**KEY CONCEPTS**

- Pacemaker malfunction soon after implantation (within 6–8 weeks) is usually due to a lead problem, such as a lead displacement, or to pacemaker programming failure, such as a pacing rate too slow for the patient’s needs.
- Pacemaker malfunction arises in a limited number of ways: failure to pace, oversensing, undersensing, and pacing at an inappropriate rate (too fast or too slow).
- With lithium-iodine batteries, abrupt failure is an unlikely cause of pacemaker malfunction.
- If a patient with a pacemaker presents with a fever of unclear etiology, pacemaker lead infection and endocarditis should be considered.
- Because paced ventricular complexes are conducted with a left bundle branch block pattern, a paced rhythm obscures the electrocardiographic diagnosis of acute myocardial infarction.
- Magnet application does not turn off a pacemaker. It does convert an inhibited or noncompetitive pacemaker to one that is not inhibited. Fixed-rate pacing and competition with the pacing underlying rhythm occur.
- Defibrillation is safe in patients with a pacemaker or ICD if paddles are placed at least 10 cm from the subcutaneous implant site of the device. Alternatively, anteroposterior defibrillation with adhesive defibrillation electrodes can be performed. There are no reports of injury to rescuers from ICD discharges during manual chest compressions.

Heart failure (HF) is a debilitating cardiac condition characterized by poor exercise tolerance and chronic fatigue along with high morbidity and mortality. Heart failure may be defined as the pathophysiologic state in which the heart is incapable of pumping a sufficient supply of blood to meet the metabolic requirements of the body or requires elevated ventricular filling pressures to accomplish this goal. The caveat that filling pressures must be normal acknowledges that a failing heart may continue to maintain systemic perfusion by using the compensatory Frank-Starling mechanism of preload reserve, resulting in the maintenance of normal stroke volume despite reduced ejection fraction. Conversely, low filling pressure with hypoperfusion indicates a pump-priming problem distinct from cardiac disease.

A complex neurohormonal regulatory relationship exists between the heart and multiple organ systems. Feedback loops mediated through a variety of vasoactive substances secreted by the kidneys, autonomic nervous system, adrenals, lungs, and vascular endothelium are most important. Perturbations of function in any of these organs affect the others (Fig. 79-1). Accordingly, the cardiovascular system must be viewed as a dynamic one, continually adapting to optimize organ perfusion. Dysfunction of the heart or any component of the system results in hormonal and other compensatory responses, some of which are not precisely titrated and may themselves be maladaptive over time.

HF is a progressive disease that begins long before symptoms and signs are evident. It is initially characterized by adaptive neurohormonal activation of the renin-angiotensin-aldosterone system, sympathetic nervous system, natriuretic peptides, endothelin, vasopressin, and other regulatory mechanisms. Various resultant inflammatory mediators are important in the pathogenesis of chronic HF by contributing to peripheral vascular disturbances and cardiac remodeling. Neurohormonal activation initially compensates for circulatory system dysfunction, but these mechanisms eventually lead to increased mechanical stress on the failing heart, causing maladaptive electrical and structural events, further impairment of systolic and diastolic function, and progressive cardiac fibrosis and apoptosis. In many circumstances, HF occurs as a consequence of pathologic conditions involving the renal, peripheral vascular, or pulmonary system. The degree of myocardial dysfunction depends on both the amount of primary myocardial disease and the functional status of these other organ systems. Increasing knowledge of these neurohormonal interactions is leading progressive improvement in the management of HF, with a shift from a hemodynamic to a neurohormonal model.

**EPIDEMIOLOGY**

HF represents the only significant cardiovascular disease that is increasing in prevalence in our society and is a common cause of poor life quality and premature death. Nearly 5 million people in the United States have been diagnosed with HF, and almost 550,000 new cases are diagnosed annually. The incidence approaches 10 per 1000 in people older than 65 years. Decompensated HF is the most common reason for hospital admission in this age group and also the most common reason for readmission within 60 days of discharge. This prevalence results in an annual estimated health care cost of $20 billion to $50 billion. The aging population, coupled with improvements in the medical therapy of HF, will result in an increased prevalence of this disease.

HF carries a 50% mortality at 5 years after symptom onset. One third of the patients with the most severe disease die within the first year after diagnosis. Females have a survival advantage over males. Progressive hemodynamic deterioration accounts for approximately 50% of deaths, but sudden death resulting from malignant ventricular dysrhythmias occurs in up to half of the patients. Medical therapy has not significantly decreased sudden dysrhythmic deaths but has improved overall outcome from pump failure. Multiple medical therapies including beta-blockers decrease the death rate by improving functional status and slowing progression of pump dysfunction.

The prognosis in HF is related to a number of factors, including age, left ventricular ejection fraction, exercise tolerance, plasma norepinephrine and B-type natriuretic peptide (BNP) levels, cardiothoracic ratio on chest radiograph, electrocardiogram (ECG) evidence of left ventricular hypertrophy or atrial fibrillation, renal function, and the presence of ventricular dysrhythmias. One third to one half of patients with HF have some degree of renal insufficiency, which is one of the strongest predictors of mortality in patients with HF. The American Heart Association (AHA) and American College of Cardiology (ACC) guidelines define HF related to systolic dysfunction as a left ventricular ejection fraction less than 40%. Diastolic dysfunction, a pathologic condition involving failure of diastolic ventricular relaxation with consequent high filling pressures, may exist in up to half of older populations with HF.
Figure 79-1. The neurohormonal model of HF describes a complex interdependence among many organ systems of the body in which functional disturbances in any one cause complex compensatory changes in the others that are eventually maladaptive. Correction of organ system dysfunction by medications and other interventions may result in the correction of these perturbations.

- **CELLULAR MECHANISMS**

The heart is composed of a mass of individual striated muscle cells (myocytes) that form a branching syncytium. Each myocyte contains a central nucleus, mitochondria, an intracellular tubular system termed the sarcoplasmic reticulum, and numerous cross-banded strands termed myofibrils that traverse the length of the myocyte. The myofibrils, in turn, contain multiple subunits called sarcomeres. They form the basic functional unit of myocardial contraction and are arranged in series. Sarcomeres occupy approximately 50% of the mass of myocardial cells and are composed of the contractile proteins actin and myosin along with the regulatory proteins troponin and tropomyosin. These proteins are surrounded by invaginations of the myocardial cell membrane (sarcolema) and the sarcoplasmic reticulum.

The sarcomere ranges in length from 1.6 to 2.2 µm, depending in part on the tension exerted on the muscle before contraction (preload). Sarcomere contraction occurs when the thin, double-helix actin is exposed to the thick myofilament myosin in the presence of Mg$^{2+}$ and adenosine triphosphate (ATP). This interaction and thus myocyte contraction as well as relaxation are controlled by the intracellular Ca$^{2+}$ level. When intracellular Ca$^{2+}$ is increased, it binds to the contraction regulatory protein troponin, which causes a conformational change in tropomyosin that exposes actin to myosin. In the presence of ATP, linkages are rapidly made and broken between actin and myosin, causing the actin to slide along the myosin filaments. This process generates muscle tension and ultimately myocyte contraction. A decrease in intracellular Ca$^{2+}$ level reconfigures the troponin-tropomyosin complex in such a way that myosin and actin linkages are broken, allowing sarcomere relaxation. Intracellular ionic calcium is the principal mediator of the inotropic state of the heart and is mainly stored and regulated by the sarcoplasmic reticulum. Most positive inotropic agents, including digitalis and catecholamines, act by increasing the availability of intracellular calcium in the vicinity of the myofibrils.

The normal cardiac index is 2.5 to 4.0 L/min/m$^2$ at rest. It is determined by the contractility, preload, afterload, and heart rate. In normal hearts, the collective force of contraction of the cardiac chamber is the sum of the forces generated by the individual myocytes. Myocyte force is in turn a function of the ability of the contractile proteins to generate power (inotropic state or contractility) as well as the degree of sarcomere stretch at the start of contraction (preload). Stretching the sarcomere progressively toward its optimal length of 2.2 µm increases the force of contraction by allowing the maximum number of actin-myosin myofilament interactions. This forms the basis of the Frank-Starling relation, which states that within physiologic limits, the force of ventricular contraction is directly related to the end-diastolic length of cardiac muscle. Contractility may be affected by a host of factors.

Multiple physiologic depressants (e.g., hypoxia, hypercarbia, acidosis, and ischemia) and pharmacologic depressants (e.g., many cardiac antidysrhythmic agents, calcium channel blockers, beta-blockers, barbiturates, and alcohol) decrease myocardial contractility. Correcting physiologic myocardial depressant factors and discontinuing certain medications with negative inotropic properties are important first steps in managing patients with HF. Inotropic agents enhance contractility and may improve hemodynamics both acutely, such as with catecholamines, and chronically, with cardiac glycosides.
Preload is the amount of force stretching the myofibril before contraction. In the intact ventricle, preload is produced by the venous return into the chamber resulting in stretch of the myofibrils constituting the chamber walls. The volume filling the chamber also results in the development of pressure that can be measured clinically in either ventricle. The pressure measured within a chamber is determined by both the volume stretching the chamber wall and the compliance characteristics of the muscle. For this reason, pressure is only an indirect reflection of the preload. Changes in compliance may occur acutely with ischemia or chronically with hypertrophy, and they may substantially alter the relationship between chamber volume, pressure, and preload (Fig. 79-2). These considerations notwithstanding, the bedside measurement of the pulmonary artery occlusion pressure (PAOP), an indirect measure of left ventricular (LV) filling pressure, by a balloon flotation pulmonary artery catheter remains an occasionally useful clinical tool in estimating preload of the left heart in complex clinical situations.

Optimal preload is the filling pressure that stretches ventricular myofibrils maximally and leads to the greatest stroke output per contraction. The actual optimal PAOP is unique for each patient because it is affected by the loading conditions and compliance characteristics. For example, patients with acute myocardial infarction tend to have stiffer, less compliant left ventricles. In these patients, optimal PAOP ranges are higher. Irrespective of the inotropic state of the ventricle, optimizing preload results in the maximum stroke output for that ventricle (Fig. 79-3). Ventricles with normal compliance accommodate larger volumes before the chamber pressure rises. Accordingly, if pressure is used to estimate preload, the normal ventricle has more dramatic increases in stroke output for similar increases in filling pressure (steeper Starling curve). The risk of pulmonary edema increases when PAOP rises significantly above normal ranges (6–12 mm Hg). In patients with low colloid osmotic pressures secondary to hypoalbuminemia, pulmonary edema may occur at even lower filling pressures.

Afterload represents the mural tension on myocardial cells during contraction. It is determined by the total peripheral vascular resistance and the cardiac chamber size. The peripheral resistance is affected by the total cross-sectional area of the circulation, the blood viscosity, and other factors. The arterioles are the major resistance vessels in the circulation. Flow is directly proportional to the fourth power of the vessel radius (Poiseuille’s law). The larger the ventricular cavity, the more mural tension and thus myocardial work is required during contraction (law of Laplace). Failing hearts cannot overcome increases in peripheral resistance in order to eject blood (Fig. 79-4). In the presence of this afterload mismatch, these ventricles dilate further, increasing their end-diastolic volumes such that stroke volume is maintained, even with decreasing ejection fraction (preload reserve). Failing hearts are therefore extremely afterload sensitive.

For clinical purposes, afterload can be thought of as the pressure against which the heart must pump to eject blood. Blood pressure (BP) is determined by the product of the systemic vascular resistance and flow (BP = SVR × CO). Hypertension is a major cause of HF in 91% of cases. Patients with HF and low cardiac output (CO) tend to maintain blood pressure by peripheral vasoconstriction mediated mainly by endogenous catecholamines and the renin-angiotensin-aldosterone system. Afterload reduction may be beneficial because it allows the conversion of pressure work into flow.
Figure 79-5. Arterial dilators decrease arterial resistance and result in increased cardiac output. Venodilators decrease venous return to the heart and relieve pulmonary congestion. Balanced agents (nitrprusside and angiotensin-converting enzyme inhibitors) do both. Decreased mural tension reduces myocardial oxygen demand (MVO₂) and may relieve ischemia. LV, left ventricular.

PATHOPHYSIOLOGY OF ACUTE PULMONARY EDEMA

Pulmonary edema is classified clinically into cardiogenic and noncardiogenic forms. Most patients in the emergency setting with pulmonary edema have the acute cardiogenic variety, which results mainly from elevated pulmonary capillary hydrostatic pressure. Most commonly, cardiogenic pulmonary edema occurs with acute myocardial ischemia or infarction, cardiomyopathy, valvular heart disease, or hypertensive emergencies. In contradistinction, noncardiogenic pulmonary edema generally results from an alteration in the permeability characteristics of the pulmonary capillary membrane. The alteration may have such diverse causes as systemic sepsis or septic shock, inhalation injuries, drugs and toxins, aspiration syndromes, the fat emboli syndrome, neurogenic causes, and high altitude.

Cardiogenic pulmonary edema results primarily from increases in pulmonary capillary hydrostatic pressure that force a protein-sparse plasma ultrafiltrate across the pulmonary capillary membrane into the pulmonary interstitium. As in all forms of pulmonary congestion, this increase in fluid flux immediately results in an increase in the lymphatic drainage of fluid from the lung. This compensatory mechanism may quickly become overwhelmed if large amounts of edema begin to accumulate in the pulmonary interstitium, ultimately leading to alveolar flooding.

The increase in left ventricular end-diastolic pressure that causes the rise in pulmonary artery occlusion pressure may have a variety of causes, particularly myocardial ischemia. Increases in left ventricular end-diastolic pressures do not always reflect increases in plasma volume, although they generally do in patients with chronic HF. In patients with chronic HF, neurohumoral mechanisms generally result in plasma volume expansion. In patients suffering from acute-onset cardiogenic pulmonary edema (as may result from acute myocardial ischemia, infarction, or abrupt increases in afterload), plasma volume is generally not expanded and may, in fact, be contracted. In this scenario, the acute challenge to a ventricle with minimal reserve results in an immediate decrease in ventricular compliance (diastolic dysfunction), with generation of high left ventricular pressures, although there is no change in volume (see Fig. 79-2). The pressures are reflected backward to the pulmonary capillaries, resulting in pulmonary edema. Volumes as large as 1 or 2 L may leave the plasma over a short time and create serious respiratory compromise.

Plasma volume studies in patients with acute cardiogenic pulmonary edema reveal that they have substantially lower plasma volumes than control patients. As therapy progresses, the plasma volume may expand as fluid is reabsorbed from the interstitial pulmonary space back into the vascular space. These changes are reflected by initial hemococoncentration as evidenced by higher hematocrits and colloid osmotic pressures.

It is important to understand this pathophysioic scenario when treating patients with both acute pulmonary edema (APE) and systemic hypotension because despite the presence of pulmonary congestion, these patients may have low plasma volume (low preload) and be in need of fluid challenge to rapidly restore preload, cardiac output, systemic perfusion, and blood pressure. Thus, careful volume infusion with aliquots of normal saline is usually the most appropriate initial resuscitation response for the hypoperfusing patient with acute-onset cardiogenic pulmonary edema.

COMPENSATORY MECHANISMS

Increase in Stroke Volume

Increased stroke volume occurs in response to an increase in preload (Frank-Starling mechanism). This compensatory mechanism is immediate and effective in improving cardiac output in response to acute systemic demands. It is a limited response, however, because myofibril stretch to a sarcomere length beyond 2.2 µm does not further increase and may actually reduce stroke output. Also, this mechanism greatly increases myocardial oxygen demand, which may lead to dysfunction in the setting of significant coronary artery disease.

Increased Systemic Vascular Resistance

Increased systemic vascular resistance results in redistribution of a subnormal cardiac output away from skin, skeletal muscles, and kidneys to maintain normal blood flow to the brain and heart. This increased afterload also increases myocardial work greatly.

Development of Cardiac Hypertrophy

Development of cardiac hypertrophy is the primary chronic adaptation of the heart to compensate for pump failure. This hypertrophy occurs mainly by increasing the number of myo-
fibrils per cell, as the heart has very limited ability to produce new cells (hyperplasia). New myofibrils arrange in series in response to an increase in chamber volume (leading to dilation over time) and in parallel when responding to higher pressure loads (leading to increased chamber wall thickness). In addition to myofiber hypertrophy, mitochondrial mass expands, leading to additional ATP provision for the expanded myofibrillar mass.

Initially, hypertrophy leads to improved function of each myocardial cell but at a higher energy cost. Unfortunately, capillary mass may not increase significantly in response to myocyte hypertrophy. In addition, hypertrophy is associated with myosin synthesis shifts from \( V_1 \) to \( V_3 \) isoforms, with related slowing of the rate of contraction, prolongation of the time to peak tension, and reduced rate of relaxation. With the continued influence of volume overload, myofibrillar mass expands more than mitochondrial mass and relative capillary blood flow is reduced, leading to progressive myocyte death (apoptosis) with fibrosis and increased stress on the remaining myocytes. This process appears to be a particular problem with aging, in which substantial diffuse loss of myocytes, increased fibrosis, and reactive hypertrophy of remaining myocytes are demonstrated. Thus, the hypertrophic response, if allowed to continue, eventually becomes a destructive process that accelerates myocyte death and reduces pump function.

## NEUROHORMONAL MECHANISMS

Neurohormonal mechanisms maintain blood pressure and vital organ perfusion and are activated by left ventricular dysfunction. Regrettably, these neurohormonal mechanisms also increase the hemodynamic burden and oxygen consumption of the failing ventricle and are counterproductive on a chronic basis.

### Renal Neurohormonal Response

Decreased glomerular perfusion results in a reduction in the renal excretion of sodium. Renal arteriolar and adrenergic receptors stimulate renin release by the juxtaglomerular apparatus. Renin facilitates the conversion of the hepatically produced protein angiotensinogen to angiotensin I, which is further converted to angiotensin II by angiotensin-converting enzyme (ACE). Angiotensin II is a potent vasoconstrictor and also an important stimulus for aldosterone release by the adrenal cortex. Aldosterone increases renal sodium retention and potassium excretion.

Renal adaptation to hypoperfusion occurs mainly through production of vasodilatory hormones such as prostacyclin, along with prostaglandins \( \text{PGI}_2 \) and \( \text{PGE}_2 \). Aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) interfere with prostaglandin synthesis by inhibiting cyclooxygenase. Accordingly, except for the useful antiplatelet effect of aspirin, NSAIDs optimally should be avoided in patients with chronic HF because they may contribute to acute renal insufficiency with concomitant salt and water retention.

### Central and Autonomic Nervous System Neurohormonal Response

The heart and great vessels contain sensory receptors that detect changes in perfusion. Metabolic receptors in muscles also exert inhibitory and excitatory influences on brainstem vasomotor neurons. Arginine vasopressin (antidiuretic hormone) is released from the pituitary gland in response to decreases in perfusion. Elevated vasopressin levels in HF increase volume overload while decreasing osmolality. This adversely affects hemodynamics and cardiac remodeling while potentiating effects of angiotensin II and norepinephrine. Vasopressin antagonists may hold promise in HF.

HF results in a generalized stimulation of sympathetic activity and inhibition of parasympathetic tone. Increased sympathetic outflow results in the release of increased epinephrine and norepinephrine from the adrenal glands and norepinephrine at peripheral sympathetic nerve endings. These elevated catecholamine levels stimulate surface receptors in the heart and blood vessels, increasing cardiac contractility, heart rate, and vascular tone. The resulting increased venous tone augments preload, which tends to maintain stroke output (preload reserve). Increased arterial smooth muscle tone increases afterload, which is deleterious to a failing ventricle incapable of maintaining stroke output against this resistance to flow.

Afterload reduction improves stroke output as pressure work is converted to flow work (see Fig. 79-5). Adequate preload must be maintained to achieve optimal benefit. Acutely, arterial blood pressure is improved and cardiac output increased by catecholamines. Chronically, a decrease in the number and affinity of surface catecholamine receptors occurs in myocardial tissue, reducing responsiveness to epinephrine and norepinephrine. Elevated catecholamines adversely affect myocardial perfusion, leading to progressive apoptosis and cardiac fibrosis.

### Cardiac Neurohormonal Response

Increases in myocardial wall stretch activate the release of cardiac natriuretic peptides, which are structurally related peptides that are important in volume and sodium homeostasis. They include atrial, BNP, and C-type natriuretic peptide. All are elevated in patients with left ventricular dysfunction. The natriuretic peptides promote water and sodium excretion, promote peripheral vasodilation, and inhibit the renin-angiotensin-aldosterone system. A variety of natriuretic peptide receptors exist on endothelial cells, vascular smooth muscle cells, renal epithelial cells, and in the myocardium. Circulating natriuretic peptides are greatly increased in HF as a result of increased synthesis. In early HF, they play a key role in compensation for left ventricular dysfunction. Attenuation of the renal response to natriuretic peptides occurs as HF progresses.

### Vascular Endothelial Neurohormonal Response

Endothelial function locally regulates vasomotor tone. A family of endothelins—ET-1, ET-2, ET-3, and ET-4—are produced by endothelial and smooth muscle cells as well as neural, renal, pulmonary, and inflammatory cells. This occurs in response to hemodynamic stress, hypoxia, catecholamines, angiotensin II, and many inflammatory cytokines. ET-1 is the most important endothelin and exerts its main vascular effects, vasoconstriction and cell proliferation, through specific ET\(_A\) and ET\(_B\) receptors on vascular smooth muscle cells. ET\(_B\) receptor stimulation by ET-1 also increases prostacyclin and nitric oxide (NO) release, causing vasodilation. ET-1 plasma levels are elevated in patients with HF, correlate with symptoms as well as hemodynamic severity, and are associated with an adverse prognosis. Infusion of a mixed ET\(_A/B\) antagonist, bosentan, improves systemic and pulmonary hemodynamics in both acute and chronic HF. Selective ET\(_A\) and mixed ET\(_A/B\) receptor antagonists show promise for hemodynamic and symptomatic improvements in patients with HF.

Nitric oxide plays a critical role in the homeostasis of cardiac function. Reduced synthesis or increased degradation of NO
at the endothelial level is detrimental in HF. Nitric oxide-mediated endothelial dysfunction may represent the earliest stage of target organ damage, which ultimately leads to hypertensive heart disease and HF.\(^{29}\) Virtually all cell types constituting the myocardium produce NO. One of the three recognized nitric oxide synthase isoforms, inducible NOS, may produce excessive NO and suppress cardiac myocyte function in HF.\(^{30}\)

**MYOCARDIAL PATHOPHYSIOLOGY**

Understanding HF requires recognition of the underlying pathologic conditions resulting in progressive myocardial dysfunction as well as the adaptive responses to this disease process. If properly recognized, precipitating causes of acute decompensation of cardiac function can usually be more effectively treated than the underlying chronic condition. The short-term prognosis in patients who have an acute precipitating cause of HF is generally favorable, provided an effective therapeutic intervention is available. The prognosis is more guarded when the underlying disease process has progressed to a decompensated state.

**PRIMARY DISEASE PROCESSES RESULTING IN HEART FAILURE**

HF can result from primary disease of the coronary arteries, myocardium, cardiac valves, pericardium, peripheral vessels, or lungs. Often, determining the etiology of HF is simpler early in its course than during its later stages.

**Coronary Artery Disease**

In developed countries, atherosclerotic coronary artery disease remains the leading cause of HF, present in almost 70% of patients in multicenter HF trials.\(^{31}\) Acute coronary thrombosis leads to focal myocardial necrosis, with resultant myocardial fibrosis and scarring. This process leads to areas of dyskinesis that result in a decreased ejection fraction. When approximately 40% of the left ventricular muscle mass is acutely infarcted, cardiogenic shock ensues. Aneurysmal dilation of infarcted areas with paradoxical motion during systole may disproportionately decrease the ejection fraction. Transient loss of contractile function may result from episodes of myocardial ischemia that do not cause frank necrosis or from an ischemic zone surrounding an infarct. This “myocardial stunning” may persist for several days. Due to improved treatment of acute coronary syndromes, the rates of death and HF are decreasing.\(^{32}\)

Chronic coronary insufficiency leads to a more diffuse myocardial fibrosis termed ischemic cardiomyopathy. Revascularization of ischemic but not infarcted myocardial tissue provides a survival benefit in patients with HF related to ischemic left ventricular systolic dysfunction. Diseases affecting the coronary microcirculation, such as vaso-occlusive sickle cell anemia and diabetes mellitus, result in similar pathology. Compensatory mechanisms may occur after large myocardial infarction and progressive cardiac disease, which are collectively termed ventricular remodeling. They include cardiac dilation, reactive hypertrophy, progressive fibrosis, and changes in wall configuration. These may result from elevated chamber filling pressures as well as neurohumoral factors.

**Cardiomyopathy and Myocarditis**

The cardiomyopathies are a group of disease processes that primarily affect the myocardium (see Chapter 80). Myocardial diseases resulting from coronary, valvular, and pericardial pathologies are excluded. Cardiomyopathy is categorized as primary, in which the cause is unknown, or secondary to some identifiable cause. Clinically, patients with cardiomyopathy tend to present with three forms—dilated, hypertrophic, or restrictive—each of which is associated with heart failure. The specific cardiomyopathy syndromes and myocarditis, which may also cause heart failure, are discussed in Chapter 80.

**Valvular Heart Disease**

Cardiac valvular disease is the third leading cause of HF, after ischemic heart disease and dilated cardiomyopathy. Acute valvular dysfunction, such as acute mitral regurgitation secondary to papillary valve rupture, may precipitate fulminant HF. Most acute valvular dysfunction involves either the mitral or the aortic valve and usually results in fulminant regurgitation. Acutely stenotic lesions are predominantly restricted to mechanical catastrophes of prosthetic valves. Typical murmurs may be difficult to appreciate or even absent in acute valvular insufficiency because of early equilibration of pressures across the defective valve. Accordingly, patients may present in extremis with fulminant pulmonary edema. Valvular disease is discussed in Chapter 81.

Mitrail insufficiency and aortic stenosis are most commonly associated with chronic HF. Knowledge of the precise valvular pathology may have important implications for emergent HF therapy. For example, patients with decompensated aortic stenosis should generally not receive vasodilator agents, which cannot increase flow across a fixed obstruction. Patients may become hypotensive due to reduced preload, with resultant decreased systemic and coronary perfusion. On the other hand, patients with mitral regurgitation benefit greatly from vasodilators, which improve antegrade flow by reducing afterload.

**Pericardial Diseases**

Pericardial diseases may significantly affect ventricular function, decreasing cardiac output and increasing intracardiac pressures, with cardiac tamponade occurring at the extreme. These are discussed in Chapter 80.

**Pulmonary Disease**

Chronic obstructive pulmonary disease (COPD) has a 20 to 30% prevalence in HF and may obscure recognition of HF.\(^{33}\) Pulmonary dysfunction reduces myocardial oxygen supply while increasing the demand for cardiac output by perfusing all tissues with suboptimally oxygenated blood. Hypoxia leads to pulmonary arteriolar vasoconstriction, which reduces lung vascular bed area, elevating pulmonary artery pressures. Chronic increases in pulmonary arterial pressure lead to right ventricular hypertrophy and dilatation. When compensatory mechanisms fail, the patient develops right-sided HF (cor pulmonale), usually with left ventricular output preserved, at least at rest. Causes of acute cor pulmonale such as a large pulmonary embolus may precipitate sudden systemic hypotension and death caused by decreased left ventricular priming.

Distinguishing primary pulmonary disease causing predominantly right-sided HF from left ventricular failure with secondary right-sided dysfunction is clinically challenging. Wheezing or rhonchi may be seen in both entities. The chest radiograph may be difficult to interpret because both presentations cause interstitial changes. Hyperinflation depresses the diaphragm, which elongates the cardiac silhouette and may mask cardiomegaly. Competition for intrathoracic space reduces lung capacity in patients with chronic HF.\(^{34}\) Natri-
uretic peptide levels may help distinguish primary pulmonary disease from HF\textsuperscript{35} (see Chapter 72).

\section*{CLASSIFICATION OF HEART FAILURE}

Many different methods of classifying HF exist, including high versus low output, acute versus chronic, right sided versus left sided, systolic versus diastolic, and forward versus backward. Early in HF, these may be useful clinical descriptors suggesting particular causes and treatment strategies. Late in the disease process, these distinctions blur.

\textbf{High-Output Versus Low-Output Failure}

High-output failure refers to a hyperdynamic state with supranormal cardiac output and low arteriovenous oxygen difference (decreased oxygen extraction ratio). Pulmonary congestion and peripheral edema occur as a consequence of elevated diastolic pressures. Diastolic dysfunction and circulatory overload contribute to the congestive symptoms. As the condition progresses, systolic myocardial dysfunction is superimposed on this background, and symptoms progress. At this point, cardiac output is normal or even low. Ultimately, untreated patients have classic HF indistinguishable from other end-stage cardiomyopathies.

A persistent hyperdynamic state results in myocardial damage over time. The hyperdynamic state may result from increased preload (e.g., renal retention of salt and water, and mineralocorticoids), decreased systemic vascular resistance (e.g., arteriovenous fistulas, pregnancy, cirrhosis, severe anemia, beriberi, thyrotoxicosis, Paget’s disease, and vasodilator medications), increased beta-sympathetic activity, or persistent tachycardia. Early recognition of the hyperdynamic state may allow effective therapy of the underlying condition, thus avoiding the development of HF.

Low-output failure is the more typical variety of HF and occurs as a result of entities such as ischemic heart disease, dilated cardiomyopathy, valvular disease, and chronic hyper tension. Low cardiac output (systolic dysfunction), high filling pressures (diastolic dysfunction), and an increased systemic oxygen extraction ratio (widened arteriovenous oxygen difference) characterize this more commonly encountered classic form of HF.

\textbf{Acute Versus Chronic Heart Failure}

The prototypical case of acute HF is that of the healthy person who develops a large myocardial infarction or acute valvular dysfunction. Chronic HF is best characterized by a disease state such as dilated cardiomyopathy, with gradual deterioration of cardiac function. In acute HF, the early presentation may be due to systolic dysfunction and hypoperfusion, often with APE resulting from the sudden reduction in chamber compliance (diastolic dysfunction) that accompanies acute ischemia or infarction. Chronic HF usually arises with symptoms related to fluid retention, with compensatory mechanisms adjusted so that normal perfusion exists, at least in the resting state.

\textbf{Right-Sided Versus Left-Sided Heart Failure}

The notion that one of the cardiac chambers can fail independently of the other is somewhat artificial. The right and left circulations are connected and, over time, output from the two chambers must be equal. Furthermore, the right and left ventricles share an interventricular septum, and dysfunction in one chamber may have immediate impact on the other. For example, acute right-sided HF from pulmonary hypertension secondary to acute respiratory failure causes bulging of the interventricular septum into the left ventricular chamber. This so-called septal shift results in decreased left ventricular preload and low cardiac output that is volume responsive. Chronic left-sided HF leads to pulmonary hypertension with resultant right-sided HF. In addition, cardiac biochemical changes such as an abnormal catecholamine response affect all chambers.

Nonetheless, the terms have some usefulness in identifying the predominant clinical presentation. Fluid accumulation “behind” the involved ventricle is responsible for many of the clinical manifestations of HF. For example, left ventricular failure leads primarily to pulmonary congestion with symptoms mostly of dyspnea and orthopnea. Patients with right-sided HF present with symptoms of systemic venous congestion, such as pedal edema and hepatomegaly.

When previously normal patients have acute pathology, the concept of left- versus right-sided HF may be clinically useful. Patients with acute myocardial infarction of the anterior wall may present with APE. Yet, unlike patients with chronic HF, they generally do not have jugular venous distention or pedal edema because the central venous pressure remains normal. A chest radiograph reveals evidence of pulmonary venous congestion, interstitial edema, and, in fulminant cases, alveolar edema. Since there has not yet been time for cardiac dilation, the cardiac shadow is of normal size.

Patients with acute right ventricular infarction typically have jugular venous distention and hypotension, but often without rales. Bulging of the interventricular septum into the left ventricular chamber results in decreased left ventricular preload. The low cardiac output and hypotension are often responsive to fluid challenge. Jugular venous distention is a sign of right-sided heart diastolic dysfunction. Failure to understand this may result in withholding of a therapeutic fluid challenge if distended neck veins are interpreted simply as a sign of HF.

\textbf{Forward Versus Backward Heart Failure}

Forward failure refers to inadequate systemic perfusion resulting from low cardiac output. The symptoms of forward failure include weakness, fatigue, oliguria, prerenal azotemia, and, in advanced cases, hypotension and cardiogenic shock. Backward failure refers to symptoms related to pressure that builds up “behind” a failing chamber. Pulmonary edema, hepatomegaly, and pedal edema are symptoms of backward failure.

\textbf{Systolic Versus Diastolic Dysfunction}

Systolic dysfunction refers to impairment of contractility. Stroke output is reduced and forward flow is compromised. Systolic dysfunction is typically caused by myocyte destruction such as occurs in myocardial infarction. Asymptomatic left ventricular systolic dysfunction in patients 45 years of age or older has an estimated prevalence of 6% and is more common than symptomatic systolic HF.\textsuperscript{36,37} Diastolic dysfunction indicates a primary problem with the ability of the ventricles to relax and fill normally.\textsuperscript{38} In many cases, normal or even supernormal systolic function is preserved. Most cases of systolic dysfunction also involve some degree of diastolic dysfunction.

Echocardiographic and nuclear imaging techniques demonstrate that 40 to 50% of patients with congestive symptoms have normal ejection fractions and suffer from diastolic dysfunction.\textsuperscript{39,40} termed HF with a normal ejection fraction.\textsuperscript{41} The proportion of HF that is primarily diastolic increases with age,
from 46% in patients younger than 45 years to 59% in patients older than 85 years. Asymptomatic diastolic dysfunction is much more common than asymptomatic systolic dysfunction, occurring in 26% of patients 45 years of age or older in one study.

Diastolic dysfunction is the predominant pathophysiology in hypertrophic and restrictive cardiomyopathies, valvular aortic stenosis, and, most important, hypertension. Diastolic dysfunction occurs predominantly as a result of one of three mechanisms: impaired ventricular relaxation, increased ventricular wall thickness, or accumulation of myocardial interstitial collagen. Impaired relaxation (lusitropic) capacity of the myocardium leads to higher ventricular filling pressure, which results in congestive symptoms. Myocardial relaxation is an active, energy-requiring process. Failure of myocytes to relax may be secondary to low intracellular energy stores. Physiologic stresses causing increased cardiac demands can precipitate lusitropic abnormalities. In chronic renal disease, mortality is higher in diastolic than systolic HF. In addition, systolic contractile abnormalities occur in one third of diastolic HF patients, and diastolic dyssynchrony in more than half, with therapeutic implications.

As with the other classification schemes, most patients with HF have components of both systolic and diastolic dysfunction. The classification of systolic and diastolic dysfunction allows specific treatment strategies. Patients with predominantly systolic dysfunction have the advantage of having intact myocardial contractile function. Stiffer hearts have steep pressure-volume curves; therefore, small reductions in diastolic filling volume, as may occur with aggressive vasodilator or diuretic therapy, may markedly decrease ventricular filling (see Fig. 79-3). This preload deficiency may compromise stroke output.

■ CLINICAL EVALUATION OF PATIENTS WITH SUSPECTED HEART FAILURE

The New York Heart Association (NYHA) classification system is a time-honored categorization for patients with chronic HF (Box 79-1). Patients who present in extremis require aggressive evaluation, monitoring, and management. Careful consideration of the differential diagnosis is symptom based. The most common manifestation of acute HF is acute respiratory distress caused by pulmonary edema. Accordingly, the differential diagnosis includes exacerbation of COPD or asthma, pulmonary embolus, pneumonia, anaphylaxis, and other causes of acute respiratory distress. Hypoperfusion may be caused by some of these as well as by sepsis syndrome, hypovolemia, hemorrhage, cardiac tamponade, and tension pneumothorax.

■ PRECIPITATING CAUSES OF HEART FAILURE

Various stresses may result in acute cardiac decompensation (Box 79-2).

### BOX 79-1 Classification System for Chronic HF: New York Heart Association Functional Classes

I. Asymptomatic on ordinary physical activity
II. Symptomatic on ordinary physical activity
III. Symptomatic on less than ordinary physical activity
IV. Symptomatic at rest

### Systemic Hypertension

Sudden elevation of arterial pressure acutely increases afterload, which may precipitate the rapid onset of HF. This is particularly common when antihypertensive therapy is abruptly discontinued. Malignant hypertension, pheochromocytoma, and other states associated with high sympathetic outflow may be implicated. Cocaine and other sympathomimetic drugs of abuse may precipitate HF.

### Myocardial Infarction and Ischemia

A new ischemic event may precipitate HF by impairing contractility and decreasing left ventricular compliance. Pulmonary edema may occur rapidly in this setting, especially when large areas of myocardium are involved. In the compromised heart, even local ischemia may precipitate HF.

### Dysrhythmia

Both tachydysrhythmias and bradydysrhythmias can severely affect cardiac output, especially when acute. Tachydysrhythmias compromise diastolic filling time and thus may reduce cardiac output. Concurrently, the shortened diastole impairs coronary perfusion and myocardial oxygen delivery while the tachycardia results in increased myocardial oxygen demand. These factors may precipitate ischemia, which may further impair contractility and exacerbate HF.

The prevalence of atrial fibrillation in patients with HF increases from less than 10% in NYHA functional class I to approximately 50% in NYHA functional class IV. Neurohormonal alterations, electrophysiologic changes, and mechanical factors create an environment in which HF predisposes to atrial fibrillation and atrial fibrillation exacerbates HF. New-onset atrial fibrillation or other dysrhythmias that affect coordinated atrial priming of the ventricular pump may seriously reduce preload, especially in disease states with reduced ventricular compliance. Significant bradydysrhythmias may also reduce cardiac output simply by reducing the number of systolic ejections per minute (CO = stroke volume × heart rate).

### Systemic Infection

Infection results in increased systemic metabolic demands. Pulmonary infection, which is common in patients with pulmonary vascular congestion, may add hypoxia to the metabolic stressors fever, tachycardia, and increased tissue perfusion. The sepsis syndrome is associated with a reversible form of myocardial depression, mediated by various cytokines,
Anemia

With chronic anemia, oxygen delivery to tissues is maintained by increased cardiac output (isovolumic hemodilution). Anemia increases in prevalence with increasing severity of HF, especially with declining renal function and increasing age. Anemia is associated with poorer survival in HF, with greater disease severity, a larger left ventricular mass index, and higher hospitalization rates. In anemic patients with HF, correction of anemia with erythropoietin and oral iron improved left ventricular systolic function, left ventricular remodeling, and BNP levels. Abrupt exacerbations of anemia increase systemic perfusion demands and, especially if coupled with reduced coronary oxygen delivery, may prompt the onset or exacerbation of HF.

Dietary, Physical, Environmental, and Emotional Excesses

Increased sodium ingestion, plasma volume expansion such as with a transfusion, increased exertion, extremes of environmental temperature, and emotional upset are some of the important factors that may prompt cardiac decompensation.

Pregnancy

Cardiac output is normally increased significantly during pregnancy, which may lead to decompensation in women with underlying valvular disease or other cardiac pathology. Partum cardiomyopathy is a type of dilated cardiomyopathy that may occur late in pregnancy or more commonly in the early postpartum period, with more than 50% of patients having normalization of left ventricular function with pharmacologic therapy.

Thyroid Disorders

HF may be a clinical manifestation in patients with previously compensated cardiac disease who develop hyperthyroidism. Hypothyroidism also adversely affects myocardial pump function. Restoration of normal thyroid function usually reverses the abnormal cardiovascular hemodynamics.

Acute Myocarditis

A variety of infectious and inflammatory diseases, including viral agents and acute rheumatic fever, may precipitously impair myocardial contractility.

Acute Valvular Dysfunction

Almost all causes of acute HF resulting from cardiac valve dysfunction are secondary to aortic or mitral insufficiency. Mitral valve papillary muscle dysfunction or rupture may result from acute myocardial infarction, whereas acute aortic insufficiency is more commonly precipitated by acute bacterial endocarditis or aortic dissection. Occasionally, acute valvular stenosis may occur, usually as a consequence of acute dysfunction of a prosthetic valve.

Pulmonary Embolus

The acute pulmonary hypertension and hypoxia that accompany pulmonary embolus may cause acute HF. Accordingly, this diagnosis should be entertained in patients who have unexplained HF and risk factors for pulmonary embolism.

Pharmacologic Complications

Patients with ischemic heart disease are often receiving ambulatory treatment with beta-blocking and calcium channel-blocking agents. These drugs have negative inotropic effects and may precipitate overt HF at higher doses. Many of the current antidysrhythmic agents may have this effect as well. Glucocorticoids, NSAIDs, vasodilator drugs, and others may result in sodium retention with substantial increases in plasma volume that may precipitate HF. NSAIDs in particular interfere with prostaglandin synthesis through cyclooxygenase inhibition, thereby impairing renal homeostasis in patients with HF. They also interfere with the effects of diuretics and ACE inhibitors. Noncompliance with medication regimens for hypertension, HF, or ischemia is the most common pharmacologic cause of acute HF decompensation. A careful medication history and evaluation of the patient’s compliance with that regimen are important in a search for precipitating factors.

EVALUATION OF HEART FAILURE

History

The presence and character of chest pain, previous heart disease, cardiac catheterization, surgery, and other focused cardiac history should be explored. With patients unable to give a history, family members and old records are sources of information. A careful review of the patient’s current medications may indicate ongoing disease processes. A more traditional history may be taken for patients who are less severely ill.

In patients with more gradual onset of HF, dyspnea on exertion is among the earliest complaints. Orthopnea is a type of dyspnea seen among patients with HF, in which supine position enhances venous return to the heart, precipitating increases in diastolic pressure. Symptoms abate when the patient props up the trunk and venous return decreases. Paroxysmal nocturnal dyspnea results from pulmonary congestion precipitated by plasma volume expansion that occurs as interstitial edema is reabsorbed into the circulation. Lower extremity venous hydrostatic pressure decreases during recumbency and is resolved by standing. Nocturia results from the same pathophysiologic process. Many historical features increase the likelihood of HF. Most predictive is a past history of HF or paroxysmal nocturnal dyspnea; the absence of dyspnea on exertion reduces the likelihood.

Physical Examination

Clammy, vasoconstricted patients with a thready pulse and delayed capillary refill may have systemic hypoperfusion despite adequate blood pressure that is maintained by intense vasoconstriction. Noninvasive assessment of blood pressure in the vasoconstricted patient with low cardiac output can be inaccurate, but cuff pressures are also not reliable (see Chapter 3). An accurate intra-arterial pressure may substantially influence the choice of therapeutic agent and should be obtained, whenever possible, before initiating inotropic or vasoconstrictor drugs. For example, a patient with a cuff pressure of 80 mm Hg might receive a catecholamine vasoconstrictor to maintain coronary perfusion pressure despite the negative impact of these drugs on afterload and ischemia. If it were known that the mean intra-arterial pressure was 80 mm Hg, the
same patient might more appropriately receive carefully titrated vasodilators such as intravenous nitroglycerin. Persistently hypotensive patients require intra-arterial pressure monitoring.

Physical examination of patients with APE resulting from acute myocardial infarction includes a search for surgically correctable lesions such as acute mitral regurgitation or ventricular septal defect. Patients with pulmonary congestion secondary to HF develop interstitial and alveolar pulmonary edema, causing reduced pulmonary compliance and decreased functional residual capacity. Crackles reflect alveolar flooding, often present in pulmonary edema. Peribronchial edema may cause wheezing, which can mimic bronchospastic disease and misdirect therapy. A positive response to bronchodilator therapy does not exclude HF. The presence of a third heart sound significantly increases the likelihood of HF, and the absence of rales decreases the likelihood.57

Diagnosis Testing in Heart Failure

The upright chest radiograph is a very useful tool to distinguish cardiogenic pulmonary edema from other causes of dyspnea, although the differentiation may be challenging in patients with COPD. Arrhythmia recognition and management are important, as is identification of acute coronary syndrome. A chest radiograph showing an enlarged cardiac silhouette with pulmonary congestion and an ECG showing atrial fibrillation, ventricular hypertrophy, or evidence of past ischemia or myocardial infarction greatly increase the likelihood of HF, whereas the absence of cardiomegaly on chest radiography and the absence of any abnormality on ECG greatly decrease the likelihood.57

The ESCAPE trial demonstrated that pulmonary artery catheterization in severe symptomatic HF increased anticipated adverse effects but did not affect overall mortality or duration of hospitalization.59 It is nonetheless still used judiciously in some complex clinical situations. Noninvasive impedance cardiography appears to be an effective and developing technology to measure cardiac output and other hemodynamic variables in HF and may obviate the need for a pulmonary artery catheter.56,63

Echocardiography is a useful diagnostic test in the evaluation of HF and can noninvasively provide measures of left ventricular function and determine structural heart disease.65 Multidetector computed tomography coronary angiography can distinguish ischemic from other forms of cardiomyopathy, but it is rarely of use in the patient with acute HF.64 Radionuclide imaging in patients with HF and significant coronary artery disease may be useful in myocardial viability testing and predicting survival response to coronary revascularization but is not of value in the management of acute HF.65

Serum levels of natriuretic peptides correlate with severity of HF and have prognostic significance.66 BNP is a neuropeptide synthesized in the ventricles in response to ventricular myocyte stretch that is released as pro-BNP and then enzymatically cleaved to NH2-terminal-proBNP (NT-proBNP) and BNP. Blood measurements of NT-proBNP and BNP help identify patients with HF and may improve the management of patients presenting to the emergency department with dyspnea.68 Rapid, whole-blood BNP assays to evaluate possible HF are approved for clinical use. The “breathing not properly” BNP Multinational Study is a prospective evaluation of patients who presented to the emergency department with acute dyspnea. BNP levels above 500 pg/mL were highly associated with HF (likelihood ratio [LR] = 8.1), and levels of 100 to 500 pg/mL were generally indeterminate (LR = 1.8). A low BNP level (<100 pg/mL) indicated that HF was highly unlikely (LR = 0.13).60,69 Elevated BNP levels may also be seen in right-sided HF related to cor pulmonale or pulmonary embolism. BNP levels are not falsely elevated in patients with end-stage renal disease, and in this setting elevation reflects ventricular dysfunction.70

The NT-proBNP and BNP levels correlate with ventricular function, NYHA classification, and prognosis.71-73 This screening modality may obviate the need for echocardiography, invasive monitoring, or both in selected clinical situations.74,76 BNP also provides a means of evaluating response to therapy. BNP levels have strong prognostic significance in ischemic heart disease. Results for large clinical trials confirm that BNP levels are the strongest predictor of outcome in HF compared with other neurohormones and clinical markers.77 There is often a disconnect between the perceived severity of HF by clinicians and the level of BNP elevation, yet BNP levels are better predictors of 90-day outcome than physician judgment.78 Patients with indeterminate BNP levels have a better prognosis than expected when physicians clinically perceive them to have NYHA class III or IV chronic HF.79 High predischARGE BNP levels are a strong, independent predictor of death or rehospitalization after decompensated HF.80

Plasma levels of troponin T in stable HF predict adverse outcomes,81 and admission BNP and cardiac troponin levels are independent predictors of in-hospital mortality in acute compensated HF.82 Concentrations of these and other biochemical markers of myocyte injury increase in the absence of discrete ischemic events in those patients with HF most likely to have adverse events.83

TREATMENT OF HEART FAILURE

Of the patients with HF presenting to the emergency department, 21% are experiencing their first episode of HF and 79% have had prior hospital visits for the same condition.84 An organized approach that (1) identifies the underlying cardiac pathology, (2) recognizes the acute precipitating event or events, and (3) controls the acute congestive state must be developed. The immediate therapeutic goals are to improve respiratory gas exchange, maintain adequate arterial saturation, and decrease left ventricular diastolic pressure while maintaining adequate cardiac and systemic perfusion. The acute congestive state may be controlled by (1) reducing the cardiac workload by decreasing both preload and afterload, (2) controlling excessive retention of salt and water, and (3) improving cardiac contractility. Patients may have a wide spectrum of symptoms and signs ranging from mild dyspnea on exertion to full-blown cardiogenic shock with hypotension and concomitant respiratory failure. The specific presentation dictates the appropriate clinical approach (Table 79-1). In most patients, sitting upright while high-flow supplemental oxygen is administered and preload is decreased with nitrates, morphine, and furosemide results in prompt improvement.

Onset of pulmonary edema may occur over several days or even weeks, but in some cases it may develop rapidly over minutes to hours. This acute, fulminant pulmonary edema is often referred to as “flash pulmonary edema,” although the origins of this term are not evident. Acute rupture of a papillary muscle during acute myocardial infarction can cause flash pulmonary edema, but it can also develop in the absence of an acute anatomic disturbance. The principles of treatment for flash pulmonary edema are the same as those for pulmonary edema of more usual onset, although the therapies may need to be delivered with greater alacrity.
Acute Heart Failure

Common precipitants of rapid-onset HF include acute myocardial ischemia or infarction, medication noncompliance or toxicity, cardiac dysrhythmia, dietary indiscretion, acute hypoxia, severe hypertension, acute valvular dysfunction, and increased hemodynamic demand secondary to trauma or infection (see Box 79-2). Iatrogenic causes of HF must also be considered, especially in patients who have recently received intravenous fluids. Patients with known renal insufficiency most often experience pulmonary edema as a consequence of salt and fluid overload, which may require prompt hemodialysis. The presence of HF on admission in patients with acute coronary syndromes is associated with increased short- and long-term rates of death and myocardial infarction.⁵⁵⁻⁵⁷

Acute Pulmonary Edema

Many patients with rapid onset of pulmonary edema demonstrate adequate systemic perfusion with elevated blood pressure because of activation of various compensatory mechanisms. The ability of the left ventricle to generate systolic pressures above 160 mm Hg indicates the presence of considerable myocardial reserve. This group of patients must be quickly distinguished from those with pulmonary edema and evidence of hypoperfusion. Hypertensive pulmonary edema is easier to manage because afterload reduction with vasodilators is extremely effective.

Most patients with APE are diaphoretic because of intense sympathetic activation. Typical findings include diffuse moist rales or rhonchi, although both may be absent with decreased ventilation in more agonal patients. Jugular venous distention is present in approximately 50%, and one third of patients have peripheral edema. An S₃ gallop may be present in up to 25%, but is often difficult to appreciate. An enlarged cardiac silhouette is seen in 70% of cases. These common clinical findings of chronic HF are prevalent among patients with APE because most patients have acute exacerbations superimposed on chronic underlying disease.⁵⁰ The absence of jugular venous distention, pedal edema, and cardiomegaly is expected in previously healthy individuals with pulmonary edema resulting from an initial episode of acute myocardial ischemia. Accordingly, a normal-size heart on chest radiograph may be consistent with acute cardiogenic pulmonary edema. In addition, normal heart size should suggest the possibility of diastolic dysfunction, COPD, or noncardiogenic pulmonary edema.

All patients with significant pulmonary edema have hypoxemia and require a high-flow oxygen face mask if spontaneously breathing. The typical acid-base disturbance of acute HF is mixed. Most patients with fulminant APE have lactic acidosis, and many also have concomitant respiratory alkalosis resulting from the tachypnea stimulated by metabolic acidosis, hypoxemia, and decreased pulmonary compliance. A substantial minority of these patients present with respiratory acidosis, even without chronic lung disease. The ratio of dead space to total ventilation ($V_D/V_T$) may be significantly increased directly

from the pulmonary edema. Respiratory muscle fatigue may supervene and result in frank hypoventilation. Patients with inadequate ventilation or with severe hypoxia require immediate ventilatory support with bag-valve-mask assisted oxygenation. Endotracheal intubation is reserved for apneic patients and those with respiratory distress, agitation, and hypoxemia not responsive to high-flow oxygen. Most spontaneously breathing patients respond rapidly to medical therapy, and most hypercarbic patients can also be managed without mechanical ventilation.

Noninvasive ventilation (NIV) techniques show promise in treating severely compromised, but not agonal, APE patients. Continuous positive airway pressure (CPAP), biphasic positive airway pressure, and CPAP plus inspiratory pressure support (noninvasive positive pressure ventilation [NIPPV]) applied by an adjustable, snugly fitting face mask increase functional residual capacity, improve oxygenation, reduce work of breathing, and result in decreased left ventricular preload and afterload by raising intrathoracic pressure (Fig. 79-6). These techniques result in more rapid restoration of normal vital signs and oxygenation than supplemental oxygen alone. Even in studies using only CPAP, fewer patients required endotracheal intubation than in control groups. The addition of pressure support (NIPPV) further reduces the work of breathing and more rapidly improves hypercarbia than CPAP alone. Selected patients may benefit greatly from these techniques when appropriately applied in conjunction with pharmacotherapy. These ventilatory therapies do not increase the risk of myocardial infarction in acute pulmonary edema. A large multicenter trial demonstrates that noninvasive ventilation provides earlier improvement in respiratory distress and related metabolic abnormalities than supplemental oxygen alone in acute pulmonary edema but does not improve short-term mortality.

**Acute Pulmonary Edema with Adequate Perfusion**

Therapeutic interventions should decrease both preload and afterload. Excessive preload reduction may result in an abrupt decrease in cardiac output, which could cause hypotension. This occurs more readily in patients with less compliant hearts, such as those with diastolic dysfunction, aortic stenosis, or acute myocardial infarction. Fluid challenge generally restores blood pressure quickly in these patients. In general, the three initial pharmacologic therapies are nitrates, morphine sulfate, and diuretics. Minimal research exists concerning the role of ACEIs in APE but they may be useful in selected clinical circumstances.

**Nitrates**

Organic nitrates activate the enzyme guanylate cyclase, leading to accumulation of cyclic guanosine monophosphate (cGMP). cGMP relaxes vascular smooth muscle by sequestering calcium in the sarcoplasmic reticulum. At lower doses, nitrates are primarily venodilators. They effectively decrease PAOP and are therefore very effective in the initial therapy of APE. At higher doses, intravenous nitroglycerin also causes arteriolar dilation that decreases blood pressure and afterload. Thus, myocardial pump function is improved while myocardial oxygen demands are decreased. Nitroglycerin may further reduce myocardial ischemia by its direct coronary vasodilator effect. Prolonged nitrate therapy over hours to days leads to tachyphylaxis secondary to depletion of intracellular sulfhydryl groups. Intermittent therapy with the smallest effective dose and occasional nitrate-free intervals minimizes tolerance.

Nitroglycerin may be initiated most expeditiously by the sublingual route, but intravenous administration and titration should begin at the earliest opportunity. Hypotension from excessive preload reduction or vagally mediated idiosyncratic reactions may occur. Nitroglycerin should also be avoided in patients who have recently taken sildenafil or similar agents because it may precipitate refractory hypotension. Patients with APE are often diaphoretic, with poor skin perfusion. Transcutaneous absorption may be erratic, and ointment applied earlier might be absorbed later in the course when skin perfusion is improved, resulting in “unexplained” hypotension. Lastly, transcutaneous nitroglycerin patches may ignite during defibrillation. These factors mitigate the use of transcutaneous nitroglycerin in patients with APE.

Intravenous nitroglycerin is a titratable agent with rapid onset and offset of action. Dosing begins at 10 to 20 µg/min by infusion pump and may be rapidly titrated upward in increments of 10 µg/min every 3 to 5 minutes. Dosages of 50 to 80 µg/min provide an antianginal effect and decrease preload in most cases. Dosages as high as 200 to 300 µg/min may be needed for maximal antihypertensive effect. High-dose nitroglycerin is effective even in severely decompensated HF.

**Morphine Sulfate**

This opioid analgesic reduces pulmonary congestion through a central sympatholytic effect and release of vasoactive histamine that causes peripheral vasodilation. The result is decreased central venous return and reduced preload, lowering PAOP. In addition, through reduced systemic catecholamines, morphine decreases heart rate, blood pressure, cardiac contractility, and myocardial oxygen consumption. Patients with APE tend to be agitated as a result of air hunger. The calming effect of morphine is advantageous in this setting. Morphine is administered in repetitive 2- to 5-mg intravenous doses titrated to effect. If oversedation results in hypoventilation, gentle stimulation usually restores ventilatory effort. In APE, mild CO2 retention does not contraindicate morphine because it results from acute alveolar flooding that is improved by the mechanisms just delineated. Patients who are obtunded at presentation should not be given morphine prior to airway support.

---

**Figure 79-6.** Noninvasive ventilation (NIV) techniques recruit collapsed alveoli and increase functional residual capacity (FRC), which improves oxygenation and reduces work of breathing (WOB). These factors tend to reduce sympathetic tone, heart rate (HR), and blood pressure (BP), relieving myocardial ischemia. NIV also acts as an afterload-reducing agent, which tends to directly improve cardiac index (CI) and systemic oxygen delivery (DO2) and consumption (VO2). PaO2, partial pressure of oxygen in arterial blood; SVI, stroke volume index; V/Q, ventilation-perfusion ratio.
Loop Diuretics

Loop diuretics inhibit sodium resorption from the renal filtrate in Henle's loop in the medulla. The result is significant increases in renal salt and water excretion. In patients with volume overload, this diuretic action lowers plasma volume, decreasing preload and pulmonary congestion. Although intravenously administered loop diuretics have a rapid onset of action (5–10 minutes), symptom relief in patients with APE often occurs much faster than it could from the diuretic effect alone. These improvements are probably the result of diuretic-induced neurohumoral changes. Furosemide is both a vasodilator, which promotes both renal PGE2 and natriuretic peptide secretion, and a vasoconstrictor, which stimulates renin release. Loop diuretics (furosemide 1 mg/kg or bumetanide 1 mg/kg) should be administered to patients with hypertensive APE. The half-life of furosemide in patients with APE is double that in healthy volunteers, and caution is required with frequent dosing.

Patients with abrupt onset of APE who do not have underlying chronic HF may have low plasma volumes at presentation. Diuresis in this group of patients may be unnecessary. Patients who fail to respond to loop diuretic administration may have severely compromised renal perfusion. Invasive hemodynamic monitoring may be beneficial in these patients. Diuretic therapy causes depletion of the important cations K+ and Mg2+, which may be significant in patients already depleted by chronic diuretic therapy or other agents. High-dose diuretic therapy in acute pulmonary edema is associated with deterioration in renal function and increased mortality.94,95

Nesiritide

Nesiritide, a recombinant human B-type natriuretic peptide, is a balanced vasodilator that reduces aldosterone and endothelin levels while increasing sodium and water excretion without a resultant reflex tachycardia. The Vasodilatation in the Management of Acute HF (VMAC) trial96 demonstrates that nesiritide is capable of symptom improvement similar to that produced by intravenous nitroglycerin in HF and, like nitroglycerine, nesiritide improves hemodynamic function while creating a diuresis (natriuretic vasodilator).97,98 Nesiritide has not been shown to be superior to nitroglycerin, however, nor to provide additional benefit when added to a treatment regimen that includes intravenous nitroglycerin. These considerations and the high cost of nesiritide relegate its use to selected cases unresponsive to other vasodilator therapy. Meta-analyses of studies of the use of nesiritide in acute HF suggest there may be increased drug-related mortality.99-102

Nitroprusside

Nitroprusside is a potent direct smooth muscle relaxing agent that acts as a balanced vasodilator to reduce both preload and afterload. Continuous intra-arterial pressure monitoring is required in patients receiving this drug to avoid precipitous hypotension. Nitroprusside is an attractive drug for patients in hypertensive crisis with pulmonary edema if intra-arterial monitoring is available and can be combined with adequate nurse staffing to avoid an inadvertent hypotensive emergency precipitated by the drug.

In patients with acute myocardial ischemia or infarction, however, nitroglycerin is preferable because it avoids the coronary steal syndrome, in which less diseased vessels dilate and “steal” flow from more diseased vessels. These patients are also particularly vulnerable to unintended hypotension, an event more likely to occur with nitroprusside than nitroglycerin. Patients with renal failure may experience thiocyanate toxicity from high-dose infusions. Cyanide toxicity, recognized clinically by the presence of agitation and lactic acidosis, may occur in individuals with a genetic predisposition.

Other Therapies

Most patients with APE and adequate systemic perfusion respond promptly to treatment with oxygen, morphine, nitrates, and diuretics. Although newer therapies, such as endothelin receptor antagonists, vasopressin receptor antagonists, beta-endorphins, adenosine antagonists, and other agents, have therapeutic potential, further studies will be required to define their utility in acute HF. Ularitide, a synthetic renal natriuretic peptide, has utility in acutely decompensated HF.109 Levosimendan, a calcium-sensitizing drug that opens ATP-dependent potassium channels, provides prompt hemodynamic improvement in acute HF.110 In cardiogenic shock treated with percutaneous coronary intervention (PCI), levosimendan improves cardiovascular hemodynamics compared to conventional isotropic therapy.111 Trials with a tumor necrosis factor antagonist fail to offer benefit in HF.112 Other previous therapies (e.g., rotating tourniquets, phlebotomy, and theophylline) have no demonstrated efficacy in APE. Endotracheal intubation should be reconsidered if the patient develops severe respiratory deterioration unresponsive to NIV, significant cardiac dysrhythmias, low cardiac output, or has ongoing chest pain.

Treatment of Acute Pulmonary Edema in Hypotensive Patients

Patients with acute cardiogenic pulmonary edema and apparent systemic hypotension present a therapeutic dilemma. Coronary perfusion in patients with coronary artery disease depends on the pressure gradient between the aorta and left ventricular chamber in diastole. The combination of hypotension and elevated left-sided filling pressure dramatically decreases coronary perfusion and leads to further impairment of contractility from increased ischemia. Accordingly, vasopressor administration to maintain coronary perfusion pressure is necessary if this set of conditions truly exists. However, vasopressor therapy can increase afterload, decrease cardiac output, increase myocardial oxygen demand, exacerbate ischemia, and precipitate dysrhythmias. Patients with this clinical condition uniformly have low cardiac output and intense peripheral vasoconstriction. In this situation, noninvasive assessment of arterial pressure is often unreliable.113 Significant gradients may exist between cuff systolic and true intra-arterial systolic pressures. Intra-arterial pressure monitoring should be instituted as early as is feasible in these patients, which may allow the judicious use of effective and myocardium-sparing vasodilator agents and avoid the use of potentially dangerous vasopressors.

If the patient is truly hypotensive, initial measures should aim to maintain or restore coronary perfusion pressure. In this setting, the patient is either in true cardiogenic shock (pulmonary edema, hypotension, and decreased peripheral perfusion) or volume depleted. Patients in true cardiogenic shock have lost as much as 40% of their ventricular muscle mass. They have both a low cardiac index (<2.2 L/min/m2) and high left-sided filling pressures (PAOP >15 mm Hg). Patients with depressed perfusion and APE may also be plasma volume depleted, with a cardiac index less than 2.2 L/min/m2 and PAOP less than 15 mm Hg. It is impossible to distinguish between these two subsets of patients by physical examination alone because both have signs of systemic hypoperfusion and
pulmonary edema. Pulmonary artery catheterization may be needed to accurately assess the hemodynamic status of these individuals.

Nearly 25% of patients with acute myocardial infarction and clinical evidence of systemic hypoperfusion have low PAOP, indicating the presence of hypovolemia. Fluid challenge alone in these patients results in restoration of hemodynamic stability in half the cases. Hypotensive patients with APE should receive a judicious fluid challenge in the form of 250-mL saline boluses over 5 to 10 minutes. If the respiratory status is not deteriorating, repeated aliquots may be administered. If hypovolemia is contributing to the hypotension, this intervention should restore blood pressure and systemic perfusion without the need for vasopressors. If the patient has true cardiogenic shock, more aggressive interventions, including inotropic and vasopressor therapy, intra-aortic balloon counterpulsation, and endotracheal intubation with mechanical ventilation, may be needed. Acute pulmonary edema with systemic hypoperfusion in the setting of acute coronary syndrome represents ischemic cardiogenic shock. Emergency coronary revascularization is the treatment of choice.113

Catecholamine Inotropic Agents

In truly hypotensive patients who are adequately volume repleted (cardiogenic shock), norepinephrine is probably the pressor of choice. It raises blood pressure and coronary perfusion pressure (α-vasoconstrictor effect) with a modest β effect for inotropy and the least overall increase in heart rate and contractility that could further increase myocardial oxygen demands. In cardiogenic shock, norepinephrine administration is a temporizing maneuver to maintain coronary perfusion pending rescue strategies such as angioplasty, intra-aortic balloon pumping, or cardiac surgery.

Intravenous inotropic agents with vasodilator properties should be reserved for hypoperfused patients with low cardiac output despite a high left ventricular filling pressure.114 Dopamine is a naturally occurring catecholamine and a norepinephrine precursor. It has a dose-dependent effect on peripheral vascular tone and is a positive inotropic and chronotropic agent. Despite previous impressions, dopamine in HF has no clinically significant perfusion-sparing effect on the kidneys at any dose.115,116

Epinephrine is a potent α- and β-agonist that maintains blood pressure and increases cardiac output. In cardiac surgery patients, it combats myocardial stunning after cardiopulmonary bypass. Dobutamine is a synthetic catecholamine that is mainly a β-receptor agonist with some α-receptor activity. It is an inotropic vasodilator at therapeutic doses and should be used with caution in patients with borderline hypotension because it occasionally reduces blood pressure further. Isoproterenol is a potent β-agonist that causes profound tachycardia and vasodilation, which would be dangerous in HF.

In patients with acute myocardial infarction or ischemia and severe left ventricular dysfunction, the use of a catecholamine may be counterproductive. Revascularization to reperfuse stunned or hibernating myocardium is preferable.

Digitalis

The cardiac glycosides inhibit the adenosine triphosphatase-dependent sodium-potassium pump in the cell membrane of the cardiac myocyte. This inhibition increases the availability of intracellular calcium to contractile proteins in myocardial cells, increasing the force of myocardial contraction, with modest inotropic effect. In the setting of acute myocardial infarction with pulmonary congestion, digitalis has minimal potency in improving hemodynamics compared with dobutamine. Digitalis preparations have little role in acute HF. Formerly, digitalis was used to control the ventricular response rate in atrial flutter or fibrillation. In this clinical situation, however, diltiazem is a more prompt and safe alternative to digoxin in normotensive patients.117

Other Cardiotoxic Agents

Amrinone is the prototype of phosphodiesterase type III inhibitors, which produce increased levels of cyclic adenosine monophosphate in the myocardium and peripheral smooth muscle. Only intravenous forms of amrinone and milrinone are approved by the Food and Drug Administration for use in HF. These intravenous vasodilating inotropic agents increase cardiac output and reduce left ventricular pressures without producing significant changes in heart rate and blood pressure. The positive inotropic effects of amrinone and dobutamine are additive, and concomitant use of both drugs appears to be better tolerated than high dosing of dobutamine alone, with lower metabolic costs. Nevertheless, long-term use of phosphodiesterase type III inhibitors reduces survival in HF in functional NYHA classes III and IV.118 These agents appear to be prodrhythmic. Amrinone and milrinone may be useful on a short-term basis in patients awaiting heart transplantation. They should be used with caution in selected patients—in general in the context of invasive hemodynamic monitoring.

Treatment of Heart Failure without Pulmonary Congestion

Occasionally, HF may lead to hypoperfusion without significant pulmonary congestion. For example, patients with dysfunction because of congestive cardiomyopathy may have had excessive diuresis or developed a dysrhythmia that has negatively affected pump function without creating pulmonary edema. Other entities to consider include septic shock and massive pulmonary embolus. Hypotension in this situation may not be pathologic because chronic adaptive changes and medical therapies may leave patients with a low blood pressure that is well tolerated. Clamminess, cyanotic extremities, altered mental status, metabolic acidosis, and decreased urine output are some of the important findings that help define significant hypoperfusion. If hypoperfusion is present, cautious volume challenge is instituted with isotonic crystalloid. Invasive hemodynamic monitoring may be indicated because chamber filling pressures help define the cardiovascular pathology.

Acute right ventricular infarction is one important cause of hypoperfusion with jugular venous distention and absent pulmonary congestion. Approximately one third of patients with acute inferior infarction have significant right ventricular involvement, which leads to inadequate pulmonary perfusion and low left ventricular priming. These patients have hypotension that is often symptomatic. Jugular venous distention is prominent, but pedal edema is usually absent. These patients often have evidence of ST segment elevation or depression in the V1 lead. Right-sided leads may provide further evidence of right ventricular infarction. Large volume crystalloid resuscitation followed by inotropic support with norepinephrine or dopamine may be required to provide adequate preload to the left ventricle and restore blood pressure.

Treatment of Chronic Heart Failure

Patients with chronic HF often have complex multiorgan dysfunction and polydrug medical regimens. In this clinical setting, the potential impact of any therapeutic intervention

ACE, angiotensin-converting enzyme; HF, heart failure.

on the entire spectrum of disease and compensatory mechanisms should be considered. For example, adding an NSAID to the medical regimen of a patient with chronic HF may negatively affect renovascular function and precipitate increased fluid retention and pulmonary edema. Chronic HF often involves a much more gradual onset of symptoms, with a slow increase in dyspnea with minimal exertion, progressive orthopnea, fatigue, and other symptoms.

U.S. guidelines approved by the AHA and ACC reflect a new classification system for chronic HF that includes four categories: patients at risk, patients with asymptomatic left ventricular dysfunction, patients with symptomatic HF, and those with refractory HF (Table 79-2). The number of patients with asymptomatic HF is approximately fourfold greater than the number of patients with symptomatic HF. Echocardiography is a very useful modality in screening for asymptomatic left ventricular dysfunction in high-risk subgroups, which has an estimated prevalence of 3 to 6% and is at least as common as systolic HF.

A most important advance in the management of HF is to modify long-term maladaptive responses as well as achieve short-term functional improvement. Ideally, treatment should be initiated in patients at risk to prevent disease progression. Atherosclerotic coronary artery disease, hypertension, diabetes mellitus, hyperlipidemia, cocaine and ethanol abuse, smoking, and obesity are significant risk factors for HF. Hypertension precedes HF in 75% of patients, particularly in blacks. Approximately two thirds of patients with systolic HF have significant coronary artery disease. Control of hypertension reduces the risk of developing HF as does control of dyslipidemias among patients with atherosclerosis. Patients with diabetes mellitus have more than a threefold increased risk of cardiac ischemic events and HF. High dietary sodium is associated with impaired diastolic relaxation. Appropriate lifestyle changes, including smoking cessation, weight reduction, restriction of salt and water intake, and modest exercise, reduce symptoms in HF and may delay progression. Excessive lipid accumulation within the myocardium is directly cardiotoxic and causes left ventricular remodeling and dilated cardiomyopathy. Substantial weight loss in patients with HF associated with obesity produces a reversal of many of the clinical manifestations and improves NYHA functional class.

There is significant variability in the adherence to HF quality-of-care issues in the United States. Initiation of proven therapeutic modalities at hospitalization leads to early benefits, including decreased risks of mortality and rehospitalization for HF.

The left ventricular remodeling process is triggered by volume or pressure overload as well as loss of cardiac myocytes (e.g., myocardial infarction). Therapeutic interventions in HF aim to slow the remodeling process. Ventricular remodeling correlates with other clinical outcomes in HF and serial measurements of various neurohormones may serve as surrogate markers of ventricular remodeling. Various antihypertensive therapies allow regression of left ventricular hypertrophy and reduce the rate of sudden cardiac death. Reverse remodeling is a new concept in which progressive left ventricular dysfunction is not simply arrested but also partially reversed. Beta-blockers, ACE inhibitors, aldosterone antagonists, and angiotensin receptor blockers are all able to inhibit or reverse remodeling.

The mainstay of treatment for chronic HF and asymptomatic left ventricular dysfunction is vasodilator therapy, which benefits pump function by reducing both afterload and preload. The most important vasodilators for chronic HF are ACE inhibitors, angiotensin receptor blockers, and nitrate therapy.
Angiotensin-Converting Enzyme Inhibitors

ACE inhibitors provide the most effective therapy for left ventricular dysfunction. ACE inhibitors increase survival in all classes of chronic HF and are also useful to prevent the development of HF in patients with myocardial infarction and asymptomatic left ventricular dysfunction.\(^{139-141}\) The actions of ACE inhibitors inhibit production of angiotensin II, producing direct vasodilation in addition to a natriuretic effect mediated by inhibition of aldosterone secretion. Additional ACE inhibitor effects include inhibition of the degradation of bradykinin and reduction of intrinsic endothelium-dependent vasoconstriction.\(^{142}\) ACE inhibitors are natriuretic vasodilators that reduce diuretic and potassium supplement requirements. Unlike other vasodilators, they do not induce reflex tachycardia.

The main side effects of ACE inhibitors are hypotension, deterioration of renal function, chronic cough, and upper airway angioedema. ACE inhibitors should be initiated at low doses with careful attention to the potential for hypotension, with concomitant reduction in diuretic and potassium supplementation. Optimal ACE inhibitor dosing, however, appears to be neglected in many patients with HF, particularly elderly patients.\(^{143,144}\) In patients with chronic HF, high-dose aspirin (>325 mg/day) may impair some clinical benefits of ACE inhibitors.\(^{145}\)

Angiotensin II Receptor Blockade

In HF patients intolerant of ACE inhibitors, angiotensin type 1 (AT\(_1\)) receptor blockers (ARBs) have utility.\(^{146}\) ARBs appear to avoid the side effects of cough and bradykinin accumulation. Two studies comparing AT\(_1\) receptor antagonists with ACE inhibitors in symptomatic HF fail to show superiority of either drug type.\(^{147,148}\) AT\(_1\) receptor antagonists have theoretical utility in patients on ACE inhibitors because angiotensin II can be produced by pathways unaffected by ACE inhibitors, and chronic ACE blockade leads to upregulation of the AT\(_1\) receptor. Addition of ARBs to maximally tolerated doses of ACE inhibitors improves hemodynamic features in patients with chronic HF and enhances peak exercise capacity while alleviating symptoms. In a meta-analysis of 17 trials comparing angiotensin II receptor blockers with ACE inhibitors, ARBs were not superior to ACE inhibitors in reducing mortality or hospitalization for HF.\(^{149-151}\) The combination of an ARB and an ACE inhibitor was superior to an ACE inhibitor alone for reducing hospitalizations but not mortality. ARBs are most useful in patients intolerant of ACE inhibitors.\(^{152,153}\) Both ACE inhibitors and ARBs allow reverse remodeling in HF.\(^{154}\)

Nitrate therapy, by virtue of a direct vasodilator effect, improves exercise tolerance in chronic HF. When used in combination with the arteriolar dilator hydralazine, it also prolongs survival in patients with HF, but less so than ACE inhibitors. However, ACE inhibitors are less effective in African Americans. A fixed-dose isosorbide dinitrate/hydralazine regimen is particularly effective in chronic HF in African Americans,\(^{155}\) reducing hospitalization by 39% and mortality by 43%.\(^{156,157}\) with these positive effects sustained over time.\(^{158,159}\) Nitrate therapy offers potential hemodynamic improvement in patients already taking ACE inhibitors.\(^{160}\) The main problem with nitrate therapy appears to be rapid drug tolerance, which can be partially addressed by daily nitrate drug-free intervals.

Calcium Channel Blockers

First-generation calcium channel blockers (verapamil, diltiazem, and nifedipine) do not improve survival in chronic HF and may precipitate clinical deterioration.\(^{161}\) Second-generation dihydropyridines (nicardipine and amlodipine) have more moderate negative inotropic effects. Amlodipine reduces fatal and nonfatal cardiac events in nonischemic but not in ischemic heart disease.\(^{162}\) There is no compelling evidence for the use of calcium channel blockers in HF, although they may be used in patients intolerant of beta-blockers, ACE inhibitors, ARBs, and combined nitrates plus hydralazine.\(^{163}\) Calcium channel blockers are indicated for the treatment of hypertension, angina, and dysrhythmias, but they should be used with caution, if at all, in patients with associated chronic HF.\(^{164}\)

Beta-blocker Therapy

Despite the apparent paradox of using agents that reduce myocardial contractility, beta-adrenergic blocking agents have significant efficacy in chronic HF. Long-term activation of the sympathetic nervous system in HF, activation of the renin-angiotensin-aldosterone system, myocardial beta-adrenergic receptor downregulation, and direct cardiotoxicity because of elevated norepinephrine levels are associated with adverse effects. An extensive meta-analysis revealed that beta-blockers in chronic HF increase ejection fraction by 29%, reduce mortality by 30%, and reduce hospitalization by 40%.\(^{165,167}\) The AHA/ACC guidelines recommend beta-blockers for all patients with symptomatic left ventricular systolic dysfunction.\(^{168}\)

Beta-blockers should not normally be initiated in acute HF. They are most useful in chronic HF associated with other conditions in which there are indications for beta-blocker therapy, including hypertension, angina pectoris, and significant dysrhythmias. Slow upward titration of beta-blocker therapy facilitates maximal tolerability.\(^{169}\) Carvedilol, a third-generation alpha- and beta-blocker with antioxidant properties, may be a particularly effective agent in chronic HF.\(^{170-173}\) In one large study comparing metoprolol to carvedilol for HF, the number needed to treat was 15 to prevent one excess death at 5 years for carvedilol.

Diuretics

Patients with chronic HF exhibit a reduced ability to excrete a sodium and water load, with abnormal cardiac and hemodynamic adaptations to salt excess.\(^{174}\) Low-dose diuretics are one of the most effective treatments to prevent the recurrence of HF.\(^{175}\) Loop diuretics, although commonly used, are associated with significant side effects, including hypovolemia, electrolyte disturbances (low K\(^+\), Mg\(^{2+}\), and Na\(^+\)), hyperuricemia, and metabolic alkalosis. The use of potassium-sparing diuretics in HF is associated with a reduced risk of death. The hypokalemia and hypomagnesemia secondary to diuretic therapy are believed to be prodrhythmic.

In patients hospitalized for HF exacerbation, admission serum sodium is an independent predictor for increased days of hospitalization for cardiovascular causes and increased mortality within 60 days of discharge.\(^{176-178}\) Persistent hyponatre-
Spironolactone and eplerenone directly antagonize aldosterone. They significantly reduce mortality while improving left ventricular function in patients with severe HF (ejection fraction <35%) already being treated with an ACE inhibitor and a loop diuretic, with or without digoxin. In the Randomized Aldactone Evaluation Study (RALES), in which patients were appropriately managed medically, 2-year mortality was 46% for the placebo group and 35% for the spironolactone group. Spironolactone reverses remodeling in patients with mild to moderate chronic systolic HF. Eplerenone, when used in addition to standard therapy, results in significant reduction in morbidity and mortality in patients post-acute myocardial infarction. Aldosterone antagonists may lead to serious hyperkalemia in the presence of significant renal insufficiency or in patients taking supplemental potassium.

**Cardiac Glycosides**

Digoxin is of benefit in patients with all degrees of chronic HF by reducing symptoms and improving quality of life and exercise tolerance. Digoxin reduces the rate of hospitalization in chronic HF, and it reduces mortality when added to ACE inhibitor and diuretic therapy. Digoxin should be used for most persistently symptomatic HF patients whose treatment already includes ACE inhibitors, diuretics, and beta-blocker therapy when HF is caused by systolic dysfunction. Digoxin appears to have no beneficial effects in mild to moderate diastolic HF.

**Other Therapeutic Interventions in Chronic Heart Failure**

**Phosphodiesterase Inhibitors**

There is no indication for long-term amrinone or milrinone therapy, which increases morbidity and mortality in patients with severe chronic HF. Other agents in this class have limited efficacy associated with increased mortality. Phosphodiesterase inhibition with sildenafil, used commonly for erectile dysfunction, is safe in HF and may have other beneficial effects, including improved cardiac output and exercise capacity. Long-term use of sildenafil in chronic HF improves exertional ventilation and aerobic efficiency.

**Statins**

Statins improve endothelial function and have anti-inflammatory, antioxidative, and immunomodulatory effects that are beneficial in patients with chronic HF. Early use of statin therapy within 96 hours of acute myocardial infarction reduces the risk of HF. Atorvastatin in nonischemic HF with moderately decreased cardiac function improved left ventricular ejection fraction, NYHA classification, and reduced serum levels of multiple inflammatory markers. Simvastatin use reduced the risk of HF by 14% in a high-risk population and also decreased the risk of major vascular effects. Statin therapy is associated with lower mortality among patients with severe HF.

**Ultrafiltration and Renal Dialysis**

Ultrafiltration reduces volume overload when diuretic therapy is inadequate. In decompensated HF, ultrafiltration may be more effective than intravenous diuretics in volume-overloaded states. Renal dialysis is important for HF treatment in end-stage renal disease. Potential complications of renal disease that may require special consideration include fluid overload, severe hyperkalemia, iatrogenic hypermagnesemia, uremic pericardial effusion, and drug toxicity (especially digitalis).

**Anemia**

An aggressive approach to anemia in chronic HF using iron supplements and intermittent erythropoietin improves NYHA class, sleep-related breathing disorders, cardiac and renal function, as well as need for hospitalization.

**Sleep Apnea–Related Respiratory Support**

Obstructive sleep apnea is more prevalent in chronic HF than previously recognized, and treatment with CPAP can be therapeutic, even improving left ventricular ejection fraction and heart transplant-free survival. Continuous positive airway pressure for central sleep apnea and HF improves nocturnal oxygenation, ejection fraction, central sleep apnea, and exercise capacity but does not improve survival.

**Exercise Programs**

Various exercise programs in chronic HF show mixed benefits in terms of functional status and quality of life, but they seem to reduce rehospitalization rates.

**Depression**

Depression is common in patients with HF, and treatment can improve psychological aspects of quality of life, although antidepressant medications may be associated with increased hospitalization and death.

**Coronary Artery Bypass Grafting and Angioplasty**

Although there is little consensus regarding the role of revascularization in the management of ischemic cardiomyopathy, registry data suggest a benefit of coronary artery bypass grafting over percutaneous coronary intervention in HF. Another study shows no advantage in preventing HF, death, or reinfarction in stable patients with occlusion of the infarct-related artery 3 to 28 days after myocardial infarction.

**Antidysrhythmic Therapy**

From 70 to 95% of patients with cardiomyopathy and HF have frequent premature ventricular beats, and 40 to 80% develop nonsustained ventricular tachycardia. An associated increased risk of sudden death exists in these patients. An extensive meta-analysis shows a 15% reduction in total mortality with amiodarone, with arrhythmic sudden death reduced by 29%. In chronic HF, amiodarone prevents the development of atrial fibrillation and converts significantly more patients with atrial fibrillation to sinus rhythm. Amiodarone is also useful in acute management of sustained ventricular tachyarrhythmias. Unfortunately, amiodarone and other antidysrhythmic agents have significant toxicities and may be prodyrshythmic. In a study of patients with post-myocardial infarction LV systolic dysfunction with or without HF, amiodarone was associated with increased early and late all-cause and cardiovascular mortality.
Implantable cardioverter-defibrillators (ICDs) have a mortality advantage over antiarrhythmics in chronic HF, although that advantage does not exist in nonischemic dilated cardiomyopathy with asymptomatic nonsustained ventricular tachycardia. In patients with previous myocardial infarction with ejection fraction below 35%, nonsustained ventricular tachycardia, and inducible ventricular tachycardia not suppressible by procainamide, ICD placement reduced sudden death by 54% at 2 years. A follow-up study demonstrated a 29% reduction in all-cause mortality with ICDs in patients with a history of myocardial infarction and a left ventricular ejection fraction less than 30%. The economic as well as clinical impact of these studies awaits further clarification.

Patients with severe HF with significant left ventricular dysynchrony benefit from atrioventricular sequential pacing. Right ventricular apical pacing is often used in chronic HF but creates abnormal left ventricular contraction, hypertrophy, and reduced pump function. Left or biventricular pacing allows more physiologic LV contraction, and both were equally effective in one study. Cardiac resynchronization therapy via left or biventricular pacing attempts to coordinate the activation of the interventricular septum and left ventricle free wall in HF with significant contractile dyssynchrony.

Optimal lead positioning using three-dimensional echocardiographic guidance maximizes the effectiveness of cardiac resynchronization therapy. Cardiac resynchronization therapy improves HF symptoms and exercise capacity, and it can reverse chronic cardiac dilation. Cardiac resynchronization therapy combined with implantable cardioverter-defibrillator greatly reduces the risk of sudden cardiac death. Cardiac resynchronization therapy reduces functional mitral regurgitation at rest. Intrathoracic impedance monitoring is available on some devices to continuously monitor hemodynamic status in HF. Also, ventricular pacing after atrioventricular node ablation appears to be more effective than pharmacologic therapy for HF with chronic atrial fibrillation.

Left Ventriculoplasty, Ventricular Assist Devices, and Transplantation

Batista and colleagues stunned the medical community in 1996 by reporting a pilot trial of partial left ventriculoplasty in the treatment of chronic HF. Simplistically, the surgery is a mechanical method of reducing left ventricular chamber size, which by Laplace’s law should make the residual myocardium more efficient by reducing left ventricular workload. After a promising beginning, left ventriculoplasty has largely been abandoned because of failure to demonstrate long-term efficacy in HF. It is still being performed with perceived benefit during coronary artery bypass grafting in patients with a dilated left ventricle.

Multiple implantable left ventricular assist devices are in various trial stages for chronic HF as a bridge to transplantation and as a surgical alternative to chronic medical management. An innovative elastic ventricular restraint device is reliably implantable in HF patients with severe left ventricular dysfunction, with apparent functional and clinical benefit. Heart transplantation is still the most effective therapy for end-stage HF; with 84% survival at 1 year, 75% survival at 3 years, and a 10-year survival rate approaching 50%. The limited availability of donors (2500 heart transplants per year in the United States), however, makes alternative surgical techniques of interest in end-stage HF. Cell transplantation techniques using neonatal or fetal cardiac myocytes or even skeletal myoblasts may become viable techniques to repair the failing myocardium, and there is increasing evidence that stem cell therapy may offer promise in chronic HF. Skeletal myoblast transplantation in a post-myocardial infarction scar experimentally improves left ventricular ejection fraction but increases arrhythmic risk. Autologous stem cell transplantation led to significant improvement in cardiac function in patients undergoing coronary artery bypass grafting for ischemic cardiomyopathy.

**SUMMARY**

Diagnosis and management of patients with HF in the emergency department remain challenging aspects of emergency medicine. Advances in the chronic medical management of HF, including the routine use of beta-blockers, ACE inhibitors, diuretics including spironolactone, and occasionally digoxin and ARBs, have resulted in sustained symptomatic improvement and reduced 5-year mortality. Despite these advances, HF exacerbation remains among the most frequent conditions resulting in emergency department visits and hospital admissions. The increased pharmacologic armamentarium presents a challenge for emergency physicians to care for HF appropriately.

Abrupt-onset APE and cardiogenic shock also require deliberate consideration of all differential diagnostic entities. A sound understanding of the pathophysiology and pharmacotherapy allows rewarding results when caring for this frequently encountered and ever challenging diverse group of patients.

**KEY CONCEPTS**

- Hypoperfusing patients with acute pulmonary edema and systemic hypotension may have acute plasma volume depletion and require a fluid challenge.
- In HF, patients with decompensated aortic stenosis should not receive vasodilator agents; in contrast, patients with mitral regurgitation benefit greatly.
- Patients with acute right ventricular infarction may present with distended neck veins but require a fluid challenge.
- Patients with acute cardiogenic pulmonary edema have low cardiac output and intense peripheral vasoconstriction. Noninvasive assessment of arterial pressure is notoriously unreliable.
- Approximately 50% of cases of HF involve mainly diastolic dysfunction.
- Aggressive treatment of risk factors for HF may prevent the development of HF.
- Neurohormonal mechanisms are ultimately deleterious in HF. Chronic therapy to negate these effects is important even in asymptomatic myocardial dysfunction.
- Emergent BNP laboratory assays objectively quantify and treat acute HF.

PERICARDIAL DISEASE (PERICARDITIS)

■ PERSPECTIVE

Knowledge regarding pericardial function and disease has increased greatly since Hippocrates described the pericardium in 460 BC as “a smooth tunic that envelopes the heart and contains a small amount of fluid resembling urine.” Galen provided the first description of a pericardial effusion and performed the first pericardial resection.1 Lancisi first described the appearance of constrictive pericarditis at autopsy in 1728. Also in the 18th century, Laennec said, “There are few diseases attended by more variable symptoms and more difficult to diagnose than [pericarditis].”1 In the 1930s, Beck described the clinical presentation of cardiac tamponade, which is known as Beck’s triad (hypotension, jugular venous distention, and muffled heart sounds).2 Despite the availability of many diagnostic tools, recognition of pericardial disease still presents a challenge.

■ ETIOLOGY

Each of the disorders listed in Box 80-1 can produce acute pericarditis, with or without pericardial effusion. In addition, most of these disorders can progress to cardiac tamponade or constrictive pericarditis.

Most cases of pericarditis are idiopathic. Even exhaustive clinical testing identifies a specific etiology in less than 20% of patients, with the remainder being considered idiopathic.

■ EPIDEMIOLOGY

Acute pericarditis is a syndrome caused by inflammation of the pericardium. Although the exact incidence is unknown, autopsy series show an incidence of pericarditis of approximately 5%. The incidence of pericarditis in the emergency department is not known.

■ PRINCIPLES OF DISEASE

Pericardial Anatomy and Physiology

The normal pericardium envelops the heart and attaches to the great vessels. It consists of parietal and visceral layers, with a narrow potential space between them. The visceral layer or epicardium adheres to the myocardium. It is separated from the parietal layer by a potential space. Each layer is 1 or 2 mm thick and is composed of elastic fibers. The position of the heart within the chest is stabilized by the attachment of the parietal pericardium to the sternum, to the diaphragm inferiorly, and to the vertebral column posteriorly. Its blood supply comes from the internal mammary artery and its nerve supply from the phrenic nerve.3

An ultrafiltrate of plasma, 15 to 35 mL of fluid, is normally contained in the pericardial space. Abnormal amounts of pericardial fluid can accumulate when the venous or lymphatic drainage of the heart is obstructed. The pericardium serves several functions: it maintains the heart’s position, lubricates the heart’s surface, prevents the spread of infection, prevents cardiac over dilation, augments atrial filling, and maintains the normal pressure-volume relationships of the cardiac chambers. Patients with congenital absence (or surgical removal) of the pericardium show few, if any, problems.

■ PATHOPHYSIOLOGY

The inflammation of pericarditis is characterized by a granulocytic and lymphocytic infiltration of the pericardium. There is an increase in the number of antibodies in the pericardial fluid.

■ IDIOPATHIC PERICARDITIS

Clinical Features

The classic symptoms of pericarditis include chest pain, pericardial friction rub, and electrocardiogram (ECG) abnormalities. A history of fever and myalgia is common. Pericarditis chest pain is usually sharp, pleuritic, and varies with respiration. It is typically relieved by sitting forward and is worsened by lying down, deep inspiration, or swallowing. It uncommonly may mimic myocardial infarction (MI) pain. Pericarditis pain is usually retrosternal, can radiate to the trapezius muscles, and may present as isolated shoulder pain. Pain can also be felt over the diaphragm.

The physical examination hallmark of acute pericarditis is the pericardial friction rub. The rub may be caused by friction between inflamed or scarred visceral and parietal pericardium or may result from friction between the parietal pericardium and adjacent pleura. It may be audible anywhere over the anterior chest wall but usually is best heard at the lower left sternal border. Friction rubs are best heard using the diaphragm of the stethoscope, with the patient in the sitting position holding his or her breath. The rub tends to be inter-

Tumors

Aortic Dissection

- Echocardiography facilitates the definitive diagnosis of pericardial effusion, although it will be normal in patients without significant effusion, and a normal echocardiogram cannot be used to exclude pericarditis. In addition, cardiac tamponade, increased pericardial thickness, pericardial tumors and cysts, constrictive pericarditis, and the congenital absence of the pericardium can all be diagnosed by echocardiography.

Some patients with acute pericarditis have elevated cardiac markers caused by myopericarditis, myocarditis, or MI. The white blood cell count and erythrocyte sedimentation rate (ESR) may be elevated but are insensitive and nonspecific. Other laboratory studies should be directed at determining nonidiopathic causes of pericarditis.

Management and Disposition

If a specific cause of pericarditis is found, therapy should be specific for that etiology. Otherwise, therapy of acute pericarditis is symptomatic. Control of inflammation will reduce pain, and a nonsteroidal anti-inflammatory drug (NSAID) is the treatment of first choice. Ibuprofen has the best side effect profile and is prescribed in anti-inflammatory doses (2400 mg/day in adults), but other NSAIDs should be equally effective. Ketorolac is expensive and has a poor anti-inflammatory effect, so it is not recommended. The patient will often report significant pain relief from the analgesic effect of the ibuprofen while in the emergency department, even before the onset of the anti-inflammatory effect. If the chosen NSAID is not effective within 1 week, a different class of NSAIDs is chosen.

Oral prednisone is the therapy for chronic pericarditis and for acute pericarditis in patients who cannot tolerate NSAIDs. Methylprednisolone and colchicine are also effective for recurrent pericarditis.

Complications

The clinical course of pericarditis is variable: 60% of patients have complete recovery within 1 week, and almost 80% have complete recovery within 3 weeks. Eighteen percent of patients can have recurrent pericarditis, which may require serial echocardiography to exclude effusion or tumor.

UREMIC PERICARDIAL DISEASE

Perspective and Etiology

Pericarditis may occur secondary to end-stage renal disease or may be associated with dialysis. It occurs more frequently in patients receiving hemodialysis than those receiving peritoneal dialysis. Acute renal failure is also associated with pericarditis. The etiology is unknown, but possibilities include toxic metabolites, bleeding of uremia, and infectious or immunologic mechanisms. The evaluation of a chronic renal disease patient with pericarditis requires a diligent search for infectious causes.

Clinical Features and Diagnostic Strategies

Patients with uremic pericarditis present with chest pain, unexplained fever, and possibly a coarse friction rub. They also may have significant effusions. The ECG in uremic pericarditis is often normal because little epicardial inflammation occurs. In a dialysis patient, cardiac enlargement on chest radiograph in the absence of signs of volume overload or congestive heart failure (CHF) should prompt consideration of pericardial effusion, and an echocardiogram will provide a definitive answer. Uremic pericarditis has an effusion that is
fibrinous and often grossly bloody. Diagnostic pericardiocentesis may be needed to exclude infection.

Management and Disposition

Uremic pericarditis is initially treated with intensive dialysis. NSAIDs are ineffective. Systemic steroids are often used but may require 1 or 2 weeks of therapy to produce a response.

Complications

Uremic pericardial effusions are among the most common causes of cardiac tamponade. Uremic pericardial effusions may be locular and difficult to drain fully with a catheter. Surgical options include a pericardial window or pericardiectomy.

POST-MYOCARDIAL INFARCTION PERICARDITIS

Approximately 20% of patients with transmural MIs experience a different quality of chest pain 2 to 4 days after infarction. This pain may represent early post-MI pericarditis. There is frequently low-grade fever and a transient pericardial friction rub. A large pericardial effusion is unusual. Early post-MI pericarditis is generally short-lived and disappears with 1 to 3 days of aspirin therapy.

The ECG changes of pericarditis usually are masked by the acute MI changes. Patients with early post-MI pericarditis have more dysrhythmias and heart failure. Pericarditis in acute MI may be an indicator of greater myocardial damage and a worse outcome.

Dressler7 reported a syndrome of fever, pleuritis, leukocytosis, pericardial friction rub, and chest radiograph evidence of new pericardial or pleural effusions in 10 post-MI patients. Frequent relapses and a high incidence of friction rubs led Dressler to describe this syndrome as a delayed complication of MI in contrast to the well-known syndrome of early post-MI pericarditis. The etiology of late post-MI pericarditis (Dressler's syndrome) may be immunologic. It may also be seen with pulmonary embolus and after pericardiotomy. Anticoagulants should be discontinued to reduce the risk of hemorrhage. Delayed, post-MI pericarditis is treated with NSAIDs or aspirin; steroids and colchicine are alternatives.
POST-TRAUMATIC PERICARDITIS

Perspective

Post–cardiac injury syndrome is defined as pericarditis after MI, cardiac surgery, or trauma. The incidence ranges from approximately 5% after MI to 30% after thoracic surgery or trauma. Pericarditis develops in 20% of patients with a penetrating cardiac injury, few of whom have cardiac tamponade.

Principles of Disease

Injury to the pericardium in blunt trauma may range from contusion to laceration or rupture. Some degree of traumatic pericarditis is found during surgery or at autopsy in many patients sustaining severe blunt trauma of the chest.

Penetrating wounds to the heart usually cause laceration of the pericardium and the myocardium, with secondary pericarditis and pericardial infections. Although the exact incidence is unknown, infection, tamponade, myocarditis, and inflammatory pericarditis may occur.

An immune pathogenesis is suggested by the development of cardiac autoantibodies, although these autoantibodies are common after injury, even in patients who do not develop pericarditis. Constrictive pericarditis occurs secondary to trauma. It may be due to pericardial blood, possibly secondary to the decreased resorptive power of damaged pericardium, with secondary fibrosis and constriction.

Clinical Features

Symptoms and signs of post–cardiac injury syndrome include pericardial rub, fever, and chest pain. Although the diagnosis is usually established clinically, confirmation by echocardiography is helpful. The interval between injury and the onset of pericarditis ranges from 4 to 12 days. During hospitalization, purulent pericarditis should be considered as a possible source of febrile illness in a trauma patient with multisystem organ failure.

Management and Disposition

Most patients respond to aspirin or NSAIDs, and the use of steroids, if necessary, does not increase the likelihood of adverse effects. Uncomplicated pericarditis secondary to blunt trauma usually resolves. The patient should be observed until other life-threatening disease processes are excluded.

NEOPLASTIC PERICARDIAL DISEASE

Perspective

Malignant pericardial tumors typically present late, which complicates diagnosis and treatment. Malignant involvement of the pericardium is observed in 3.4% of general autopsies and 2 to 31% of cancer autopsies. The most common causes are lung cancer (30%), breast cancer (23%), leukemia (9%), non-Hodgkin’s lymphoma (9%), and Hodgkin’s disease (8%). Primary malignancies of the pericardium are rare.8

Principles of Disease and Pathophysiology

The pattern of cardiac involvement by a malignant tumor is determined by the heart’s lymphatic drainage system. Small lymphatics drain into a few vessels, which perforate the myocardium and drain into an epicardial plexus. The epicardial lymphatics drain into larger vessels, which accompany the coronary arteries to the aortic root. There, they empty into the cardiac lymph nodes in the mediastinum between the innominate artery and the superior vena cava. The route of metastasis is usually retrograde from involved mediastinal lymph nodes to the relatively narrow passage at the root of the aorta. This is where obstruction to cardiac lymphatic drainage occurs.

Malignant pericardial effusions contribute directly to the patient’s death in most cases. Cardiac tamponade is common. Although the underlying disease process is often advanced when tamponade develops, the patient’s quality of life can usually be improved if tamponade is treated promptly.

Clinical Features

Primary cardiac neoplasms, such as angiosarcoma and teratoma, can present initially with symptoms consistent with pericarditis. The typical course is that of an acute pericarditis that resolves and subsequently recurs. Malignant pericardial disease is difficult to diagnose. Most patients are asymptomatic or have nonspecific symptoms, such as shortness of breath, cough, palpitations, ill-defined chest pain, weakness, dizziness, hiccups, or fatigue.

Diagnostic Strategies

The diagnostic workup for malignant pericardial effusion includes an echocardiogram, computed tomography (CT), or magnetic resonance imaging (MRI). When a pericardial effusion is identified, pericardial fluid cytology is recommended if the underlying malignancy is undiagnosed.

Management and Disposition

Malignant pericardial effusion is usually treated in the inpatient unit, and treatment may include pericardiocentesis, local instillation of sclerosing or chemotherapeutic agents, systemic chemotherapy, cardiac radiation, and pericardial window. The method chosen depends on the primary tumor and the patient’s expected length of survival.

The prognosis for patients with malignant pericardial disease depends on the type and extent of the underlying cancer. Patients with a tumor diagnosed in the emergency department should be offered admission, as should all patients who are symptomatic or hemodynamically compromised.

RADIATION-INDUCED PERICARDITIS

Fewer than 5% of patients treated with radiation therapy develop pericarditis. The incidence has decreased with modern radiation therapy techniques. The percentage of pericardial volume irradiated and the dose help determine which patients develop pericarditis. Radiation-induced pericarditis is seen most commonly in patients with Hodgkin’s lymphoma or breast cancer. Pericardial effusion and constrictive pericarditis are common. Tumor recurrence should be considered.

PERICARDIAL DISEASE RELATED TO SYSTEMIC CONNECTIVE TISSUE DISORDERS

Rheumatoid Arthritis

Pericarditis occurs in approximately one third of patients with rheumatoid arthritis (RA) during the course of their disease, usually within 3 years of the initial diagnosis. Rheumatoid pericardial disease is rarely clinically significant. Occasional
patients develop effusions, constrictive pericarditis, or cardiac tamponade. These patients usually have rheumatoid nodules, elevated circulating rheumatoid factor levels, and valvular heart disease. Pericardial involvement should be suspected in any RA patient experiencing the onset of right-sided CHF. There are no suggestive ECG or chest radiograph findings. Pericardial fluid may have rheumatoid factor or a low glucose level. Corticosteroid treatment is useful in symptomatic patients.

**Systemic Lupus Erythematosus**

Pericarditis is found in more than 50% of patients with systemic lupus erythematosus (SLE) at autopsy. The effusion is usually thick and fibrinous. Either cardiac tamponade or constrictive pericarditis may develop. Lupus erythematosus cells may be identified in pericardial fluid specimens. Corticosteroid therapy is indicated for pericardial involvement in SLE.

**Other Connective Tissue Disorders**

Approximately 33% of patients with Sjögren’s syndrome show evidence of pericarditis. Giant cell arteritis produces granulomatous myocarditis that may respond to methylprednisolone. Cardiac abnormalities, particularly pericarditis, are seen in numerous patients with mixed connective tissue disease. Other connective tissue diseases that may cause pericarditis include ankylosing spondylitis, Reiter’s syndrome, Behçet’s disease, systemic sclerosis, and polyarteritis nodosa.

**MISCELLANEOUS INFECTIOUS CAUSES OF PERICARDITIS**

Other etiologies of pericarditis include *Rickettsia conorii*, which causes Mediterranean spotted fever (treated with doxycycline), *Mycoplasma pneumoniae* (treated with a macrolide), *Nocardia asteroides* (treated with pericardectomy and long-term use of antibiotics such as sulfisoxazole), *Chlamydia trachomatis*, Epstein-Barr virus, cytomegalovirus infection, *Haemophilus actinomycetemcomitans* (treatment with chloramphenicol), and coccidioidomycosis (endemic in the southwestern United States). Viral and bacterial causes of pericarditis can coexist, such as varicella-zoster infection superinfected with *Staphylococcus aureus*. Bacterial superinfections associated with varicella are more common in children.

**PERICARDIAL EFFUSION**

**Etiology and Clinical Features**

The most common causes of pericardial effusion are viral or idiopathic pericarditis, malignancy, uremia, trauma, and radiation therapy. Drug reactions and autoimmune diseases are less common causes.

Pericardial effusion is often asymptomatic. Patients with known associated conditions (e.g., cancer or renal failure) who present with cough, fever, chest pain, or dyspnea may have an effusion.

**Diagnostic Strategies**

Pericardial effusion may present with an enlarged cardiac silhouette on chest radiograph, usually with normal pulmonary vasculature. A minimum of 200 to 250 mL of pericardial fluid is necessary to produce cardiomegaly on chest radiograph.

Echocardiography is the diagnostic modality of choice (Fig. 80-2). It easily differentiates pericardial fluid from cardiac chamber enlargement and provides information about myocardial wall motion.

CT may be useful in diagnosing pericardial effusion when the echocardiogram is technically unsatisfactory. MRI can also be diagnostic. Nuclear scans may be useful in detecting purulent pericardial effusions.

Pericardiocentesis may be performed for either diagnostic or therapeutic purposes. Elective diagnostic pericardiocentesis is indicated in cancer patients (to differentiate malignant effusion from postradiation pericarditis), for failure to respond to usual treatment, or when bacterial infection is suspected. Common complications of pericardiocentesis include induction of cardiac dysrhythmias, pneumothorax, perforation of myocardium, laceration of coronary or internal mammary arteries, and liver laceration. Echocardiographic-guided pericardiocentesis is the procedure of choice.

Pericardial fluid should be analyzed for protein, glucose, specific gravity, cell count and differential, Gram’s stain, and culture. Other tests, depending on the clinical picture, include cytology, acid-fast stain, fungal smear, and connective tissue disease screening.

The gross appearance of the pericardial fluid provides a clue to the cause. Serosanguineous effusions are associated most commonly with neoplasms, tuberculosis, uremia, radiation, and idiopathic pericarditis. Grossly bloody effusions are caused
by blunt or penetrating trauma, postinfarction myocardialupture, aortic dissection, coagulopathies, and iatrogenic
cardiac perforation. Purulent pericardial fluid is seen with
pneumonia, empyema, and sepsis.

**CARDIAC TAMponADE**

**Etiology and Pathophysiology**

Ten percent of all patients with cancer develop cardiac tamponade. Cardiac tamponade should be suspected in patients
with penetrating chest wounds. It is also common in patients
with uremic pericarditis.

Cardiac tamponade is the result of compression of the myo-
cardium by the contents of the pericardium. This compression
is usually caused by fluid, but it may be caused by gas, pus,
blood, or a combination of factors.

Cardiac tamponade is a physiologic continuum reflecting
the amount of fluid, the rate of accumulation, and the nature
of the heart. The three stages necessary for tamponade to
develop are fluid filling the recesses of the parietal pericar-
dium, fluid accumulating faster than the rate of the parietal
pericardium's ability to stretch, and accumulation that exceeds
the body's ability to increase blood volume to support right
ventricle filling pressure. The final result is increased pericar-
dial pressure, which causes decreased cardiac compliance and
decreased flow of blood into the heart, which leads to decreased
cardiac output.9

The most important factor in the development of tampon-
ade is the rate of fluid accumulation. The main pathophysi-
ologic effect is reduction of blood inflow into the right ventricle
that results in decreased stroke volume and decreased cardiac
output. The heart initially responds to tamponade by increas-
ing heart rate to maintain output. This compensatory mecha-
nism is maintained until late in the course. Decompensation
occurs quickly.

**Symptoms and Signs**

Cardiac tamponade symptoms are usually nonspecific. The
patient may complain of chest pain, cough, or dyspnea. The
classic triad of cardiac tamponade signs described by Beck is
hypotension, distended neck veins, and muffled heart sounds.10
These signs may not be present if tamponade develops quickly.

**Diagnostic Strategies**

The chest radiograph shows cardiomegaly only if there is a
large accumulation of fluid (250 mL). The ECG classically
shows decreased voltage or electrical alternans (Fig. 80-3), but
the latter is rare. Echocardiography confirms the diagnosis
when an effusion and paradoxical systolic wall motion are
seen. Thermodilution catheters can also be diagnostic, showing
equalization of right and left ventricular pressures.

**Management and Prognosis**

Initial treatment includes volume augmentation to the right
ventricle with intravenous fluids to increase the filling pressure
to overcome the pericardial constriction. Pericardiocentesis is
the treatment of choice. Enough fluid should be withdrawn to
stabilize the patient. If tamponade recurs, pericardiocentesis
may be repeated, or a drainage catheter may be left in the
pericardial space. A pericardectomy ultimately may be neces-
sary. Cardiac tamponade has a high mortality that depends on
the severity and nature of the underlying disease, the time
course of onset, and the rapidity of diagnosis and intervention.
Traumatic cardiac tamponade is discussed in Chapter 42.

**PURULENT PERICARDITIS**

**Epidemiology and Etiology**

Purulent pericarditis is a life-threatening process that is seen
most commonly in hospitalized patients with systemic illnesses
who develop sepsis. It can occur in any age group. It can be
caused by any type of infectious agent, with bacteria, especially
*Streptococcus* and *Staphylococcus*, being the most common.
*Candida* pericarditis is found in three groups of patients: in
those after cardiac surgery, those with impaired host defenses,
and those with severe debilitating underlying diseases. *Hist-

![Figure 80-3. Electrocardiogram showing electrical alternans.](image-url)
Principles of Disease and Pathophysiology

Purulent pericarditis occurs by several mechanisms: (1) spread from an adjacent infection, such as pneumonia or empyema; (2) hematogenous spread from a distant site; (3) direct inoculation of bacteria (trauma or procedure); and (4) spread from an intracardiac source. The most common mechanism is spread from a distant site.

Clinical Features and Diagnostic Strategies

Purulent pericarditis usually presents as a febrile illness lasting 2 or 3 days. Common presenting signs include tachycardia, dyspnea, hepatomegaly, elevated central venous pressure, chest pain, friction rub, and a leukocytosis. The most common presentation is a hospitalized patient with a serious underlying disease who initially improves after treatment of the primary process but later develops fever, dyspnea, and chest pain.

The diagnosis should be suspected in any febrile patient with multisystem illness who has a pericardial effusion. Pericardiocentesis is necessary to establish the diagnosis, obtain fluid for microbiologic studies, and relieve cardiac tamponade.

Management and Disposition

Pericardiectomy is the traditional treatment of choice. Indwelling catheters, coupled with lavage, antibiotics, and fibrinolytics, may avoid the need for surgery. When intravenous antibiotics or antifungals are indicated, prolonged treatment is necessary.

The overall survival rate for purulent pericarditis is approximately 30% with antibiotic therapy alone and 50% when combined with early surgical drainage. In addition to the initial complications related to sepsis and tamponade, long-term sequelae of purulent pericarditis include the development of constrictive pericarditis.

Tuberculous pericarditis is estimated to occur in 1 or 2% of patients with pulmonary tuberculosis. In Africa, it is the most common cause of pericarditis. In countries in which tuberculosis is not a major health problem, tuberculous pericarditis is most common in patients who are socioeconomically deprived or immunodeficient. Although rare, isolated tuberculous pericarditis still exists. Tuberculous pericarditis usually spreads to the pericardium by direct extension from the tracheobronchial tree, mediastinal or hilar lymph nodes, sternum, or spine.

In many patients, the chest radiograph shows an enlarged cardiac silhouette without a pulmonary infiltrate. Pericardial fluid aspirates reveal acid-fast bacilli by smear or culture (which may require 4–6 weeks to become positive) in approximately 50% of cases. Diagnostic workup should include assessment for human immunodeficiency virus (HIV).

Patients with tuberculous pericarditis should be hospitalized and observed for evidence of cardiac tamponade. Triple-drug therapy should be started in the hospital and continued for at least 9 months. Patients with chronic pericardial effusions may benefit from oral prednisone therapy. Those with evidence of pericardial thickening, constrictive pericarditis, or hemodynamic compromise should be referred for surgical treatment. The mortality rate is approximately 15% in HIV-negative patients and 20 to 35% in HIV-positive patients.

Other Causes of Pericarditis

Amyloid deposition can cause either restrictive cardiomyopathy (RCM) or constrictive pericarditis. Pericarditis can occur rarely as an extraintestinal complication of inflammatory bowel disease and is independent of the clinical course of the gut disorder.

Iatrogenic pericarditis can also occur as a complication of an implantable defibrillator or an atrial lead of a permanent pacemaker. A polymicrobial bacterial pericarditis can occur after transbronchial needle aspiration or as a complication of endoscopic variceal sclerotherapy. Rarely, pericarditis can also be caused by erosion of a foreign body, such as a sewing needle or toothpick, through the esophagus into the pericardium.

Pneumopericardium

Perspective and Etiology

Pneumopericardium and pyopneumopericardium are rare. Pneumopericardium may be caused by diseases that can lead to formation of fistulae between the pericardial and pleural space, bronchial tree, or upper gastrointestinal tract (e.g., peptic ulcer disease, carcinoma of the esophagus or stomach, and esophageal diverticulum). It may result from bronchial carcinoma or infection with gas-producing microorganisms, or it can be idiopathic. Pyopneumopericardium may result from trauma, foreign body, ingestion of caustic substances, or invasive procedures (e.g., esophagoscopy, thoracenteresis, and endotracheal intubation).

Spontaneous pneumopericardium may complicate asthma, labor, barotrauma from positive-pressure ventilation, or Val-salva maneuvers, such as might occur during weightlifting. Cocaine inhalation from positive-pressure devices can also cause pneumopericardium.

Pathophysiology

Pneumopericardium is caused most commonly by an increase in intra-alveolar pressure above atmospheric pressure, resulting in rupture of alveoli. Air dissects into the hilum and mediastinum, through the pericardial reflection on the pulmonary vessels, and into the pericardium.

Clinical Features and Diagnostic Strategies

Physical findings depend on the quantity of fluid and gas in the pericardial space. Heart sounds can be of variable intensity, change depending on body position, and have a metallic quality that may be accompanied by splashing sounds. Hamman’s sign and mediastinal crunch are the terms used for a loud,
crunching sound associated with pneumopericardium or pneumomediastinum. This is best heard with the patient in a left lateral recumbent position and is diagnostic for the presence of mediastinal air. The diagnosis of pneumopericardium is confirmed by chest radiograph, CT scan, or echocardiography. Tension pneumopericardium presents with clinical findings of acute cardiac tamponade.

Management

Stable patients with uncomplicated spontaneous pneumopericardium can usually be observed. After all other life-threatening injuries and complications are excluded, there are no expected long-term sequelae. Tension pneumopericardium should be treated with emergency pericardiocentesis.

■ CONSTRUCTIVE PERICARDITIS

Perspective and Etiology

Constrictive pericarditis may be a late consequence of viral pericarditis. Tuberculosis is still the leading cause of constrictive pericarditis in some countries. There is an increased incidence of constrictive pericarditis as a result of improved survival of patients with chronic renal disease. Other predisposing conditions include radiation, trauma, purulent pericarditis, actinomycosis, and postpericardiotomy adhesions.

Principles of Disease and Pathophysiology

Constrictive pericarditis usually results from fibrous reaction of the pericardium and is characterized by impaired diastolic filling from external cardiac compression caused by a thickened pericardium. In advanced cases, the visceral and parietal pericardial layers may be adherent. Impaired ventricular filling is the key pathophysiologic feature.

Since the pericardium limits volume, ventricular filling is rapid and completed within the first one third of diastole, after which left ventricular volume and pressure remain unchanged. Early ventricular filling followed by a period of unchanging pressure yields a corresponding dip and plateau pattern or square root sign on the left ventricular diastolic pressure curve. This suggests the diagnosis of constrictive pericarditis.

Clinical Features

The symptoms and signs of constrictive pericarditis are virtually indistinguishable from those of CHF. Dyspnea, fatigue, and weight gain are the most common complaints. Hepatomegaly, marked pitting lower extremity edema, and ascites can be seen on physical examination. The characteristic auscultatory finding of constrictive pericarditis is a pericardial knock in early diastole, and a friction rub may also be audible.

Diagnostic Strategies

The diagnosis is considered in a patient with right-sided heart failure symptoms. Heart size on the chest radiograph is typically small but may be increased by atrial enlargement. Pericardial calcification is suggestive when present on CT or MRI. Liver function tests are consistent with passive congestion. ECG findings include low QRS voltage, nonspecific ST-T wave abnormalities, and atrial dysrhythmias.

Doppler echocardiography may help differentiate constrictive pericarditis from RCM or cardiac tamponade. Cardiac catheterization and simultaneous measurement of right ven-
Cardiac System

Cardiac autoantibodies develop after myocarditis. There is also a higher concentration of IgG anti-α-myosin antibodies in patients with myocarditis and DCM than in controls. Because myocarditis is linked to the development of DCM, idiopathic DCM after myocarditis may be predominantly autoimmune in origin, resulting from either shared antigens or molecular mimicry. The amino acid sequences of the coxsackie B virus and β-myosin heavy-chain protein are more than 50% similar. An immune response to the former yields damage to the latter (molecular mimicry).

### CLINICAL FEATURES

Flulike complaints, including fever, fatigue, myalgias, vomiting, and diarrhea, are usually the first symptoms and signs of myocarditis. Altered vital signs include fever, tachycardia, tachypnea, and, uncommonly, hypotension. Tachycardia disproportionate to the temperature or apparent toxicity may occur but is a nonspecific finding. No symptom or sign is sensitive or specific. Cardiac examination is often unremarkable. When chest pain or CHF occurs at initial presentation, there is an increased likelihood of parvovirus infection, greater cardiac damage, and a worse prognosis. Other etiologies to consider include sepsis or MI.

In children, prominent physical findings include grunting respirations and intercostal retractions. Although the lungs are clear to auscultation in most patients, approximately 10 to 15% have rhonchi. This may be related to infection with RSV, which can cause these symptoms with or without associated myocarditis. Infants often have a fulminant syndrome characterized by fever, cyanosis, respiratory distress, tachycardia, and cardiac failure. When children have ventricular dysrhythmias, myocarditis and idiopathic DCM are commonly seen on endomyocardial biopsy, despite findings of a structurally normal heart by noninvasive studies.

### DIAGNOSTIC STRATEGIES

Common ECG changes include sinus tachycardia and low electrical activity. There may be a prolonged corrected Q-T interval, atrioventricular block, or acute MI pattern abnormalities.

Cardiac troponin is usually elevated. The white blood cell count and ESR are nonspecific. The echocardiographic features of myocarditis, although nonspecific, include reduced left ventricular ejection fraction, global hypokinesis, and regional wall motion abnormalities. Contrast-enhanced MR may also be diagnostic. Indium-111 anti-myosin antibodies bind specifically to exposed myosin in damaged myocardial cells, providing a noninvasive approach for the diagnosis of myocardial necrosis. With nuclear scanning, myocarditis is usually characterized by a diffuse, faint, heterogeneous uptake of anti-myosin antibody because myocyte necrosis is typically widespread. Acute MI is almost always characterized by an intense, localized uptake of antibody in the region of the occluded coronary artery.

Acute and convalescent viral titers are positive in less than 40% of cases. A fourfold rise in viral titers or a high titer of viral-specific IgM may help establish a viral etiology.

Endocardial biopsy, long considered the gold standard, has variable sensitivity and specificity (Fig. 80-4). Histologic criteria for myocarditis are present in only 5 to 30% of patients with clinically suspected myocarditis and up to half of patients with DCM. Molecular genetic probes, such as polymerase chain reaction, are used to supplement standard histologic analysis. In addition, polymerase chain reaction analysis of tracheal aspirates of intubated patients with myocarditis shows a correlation with endocardial biopsy.

### DIFFERENTIAL DIAGNOSIS

Myocarditis can masquerade as acute MI with severe chest pain, ECG changes, elevated cardiac markers, and heart failure. Patients with myocarditis are usually young and have few risk factors for coronary artery disease. ECG abnormalities may extend beyond the distribution of a single coronary artery, or there may be global, rather than segmental, wall motion abnormalities on echocardiography. In myocarditis, chest pain continues, but there are no further ischemic ECG changes.

If the differentiation of myocarditis from MI is unclear, the emergency physician may refer the patient for catheterization. Coronary angiography is usually normal in myocarditis, which should prompt consideration of endomyocardial biopsy.

The diagnosis of myocarditis should also be considered in an otherwise healthy patient who presents with symptoms and signs of new CHF or dysrhythmias.

### MANAGEMENT

The type of supportive care necessary is determined by the patient’s clinical presentation and the stage and severity of disease. This may extend from simple limitation of activity to rhythm and CHF treatment, extracorporeal membrane oxygenation, ventricular assist devices (VADs), and eventual cardiac transplantation.

Therapy is stage specific, given the three distinct phases of the disease. In the first phase, demonstration of replicating enterovirus RNA suggests that early antiviral agents, such as plecanaril or ribavirin, may be effective. Agents active at the coxsackievirus-adenovirus receptor present an intriguing, theoretical approach.

Hopes that the subacute phases of myocarditis might respond to immunosuppressive therapy are tempered by the
results of several multicenter trials, which do not establish efficacy. Efforts to identify patient and treatment subsets in which immunosuppressive therapy may be beneficial are ongoing. High-dose gamma globulin therapy has been studied in a pediatric population. High-dose intravenous immunoglobulin may be associated with improved recovery of left ventricular function and better survival during the first year after presentation.

In the chronic stage, CHF symptoms predominate and standard pharmacologic treatment for CHF is indicated. In some cases, the deterioration of cardiac function is reversible with the aid of a VAD. These devices have been used successfully over extended periods, including up to 70 days. Their use should be considered before transplantation.

**DISPOSITION**

All patients should be monitored, and those with hemodynamic instability require intensive care. Paradoxically, patients with fulminant myocarditis have the best prognosis. Complications of myocarditis include ventricular dysrhythmias, left ventricular aneurysm, and cardiac failure.

The mortality rate is 20% at 1 year and 50% at 5 years, despite optimal medical management. Ejection fraction and right ventricular function 1 year after initial presentation may be the best predictors of subsequent survival. The long-term prognosis in survivors is variable.

Patients who undergo transplantation because of myocarditis heart failure have decreased 1-year survival compared to patients transplanted for other reasons. They also have higher allograft rejection rates than other recipients. The overall 5-year survival rate for children is 70%.

**CHAGAS’ DISEASE**

Chagas’ disease is one of the leading causes of myocarditis in many countries in Latin America, particularly in Central America. Chagas’ disease is caused by the protozoan Trypanosoma cruzi with transmission by insect vectors.

Approximately 75% of seropositive patients with Chagas’ disease never have cardiac symptoms. One fourth have anginal-like chest pain, dysrhythmias, embolic episodes, heart failure, conduction abnormalities, multifocal ventricular premature contractions, and abnormal ST segment and T wave abnormalities in the precordial leads. Ventricular tachycardia is common. Syncopal or near-syncopal episodes occur in nearly two thirds of patients.

Serum parasites establish the diagnosis. Chagas’ disease should be suspected in ED patients with new cardiac symptoms and a Latin American travel history.

In more than half of those patients who die of chronic Chagas’ disease, autopsy reveals a unique left ventricular apical aneurysm or scar, which is a reliable marker of the disease. Echocardiography may also be suggestive. The extent of tissue damage correlates with the parasite load, which also can be found in histologic sections of infected tissues.

Chagas’ disease is treated with the antitrypanosomal drugs benznidazole and nifurtimox. Amiodarone may be useful to treat ventricular tachycardia. An angiotensin-converting enzyme inhibitor may be useful for CHF.

**TRICHINOSIS**

Trichinosis is caused by ingestion of the cysts of *Trichinella spiralis* in undercooked meat. The acute illness consists of fever, myalgias, muscle tenderness, neck stiffness, and a characteristic peri-orbital edema. Historically, in the United States, pork was the most commonly implicated meat, but trichinella has been eradicated from commercial domestic pork for many decades. Trichinosis in the United States is most likely to be caused by wild game, such as bear or cougar, although there are scattered reports from imported or home-raised pork. Larvae may be deposited in the myocardium, which incite an eosinophilic inflammatory reaction and necrosis of muscle fibers.

Myocardial involvement is present in approximately 20% of clinically diagnosed cases and appears in the second or third week of illness, when other symptoms are declining. Cardiac manifestations include chest pain, dyspnea, cardiomegaly, dysrhythmias, and CHF. ECG findings, such as nonspecific ST-T wave abnormalities and conduction blocks, may appear transiently, even in the absence of cardiac symptoms. Peripher al eosinophilia and an elevated ESR are common.

The diagnosis is usually established with serologic studies or biopsy of any symptomatic muscle group. Treatment usually involves corticosteroids together with antihelminthic drugs such as thiabendazole and albendazole.

**DIPHTHERIA**

The incidence of diphtheria in the United States since 1980 is 0.001 cases per 100,000 population. Most diphtheria patients in the United States are immigrants. Individuals at risk include the nonimmunized and those in contact with farm animals and unpasteurized dairy products.

Diphtheria is caused by the toxin of the gram-positive organism Corynebacterium diphtheriae. The principal manifestations are nasopharyngitis with membrane formation and respiratory obstruction, myocarditis, and polyneuritis. Myocardial involvement is clinically evident in 10 to 25% of cases and is the major cause of death. Early signs of myocarditis are tachycardia and faint heart sounds. Cardiac markers are often elevated. Prolongation of the P-R interval and ST-T wave abnormalities occur within the first 2 weeks of onset. Other ECG abnormalities, such as bundle branch block or complete heart block, precede total circulatory collapse and are associated with a poor prognosis.

Specific therapy involves high-dose penicillin and diphtheria antitoxin. Treatment with oral carnitine, a cofactor in the transport of fatty acids to mitochondria, is associated with a lower incidence of heart failure, severe conduction blocks, and decreased mortality.

**LYME DISEASE**

**Epidemiology and Clinical Features**

Lyme disease is caused by infection with the spirochete *Borrelia burgdorferi* and is discussed in Chapter 132. Lyme disease–related carditis occurs a median of 21 days after the onset of erythema migrans. Cardiac complications occur in 4 to 10% of patients. These include conduction disturbances; bundle branch block; first-degree, second-degree, and third-degree heart block; cardiac arrest; dysrhythmias; and left ventricular dysfunction.

Lyme disease-related carditis should be suspected in otherwise healthy persons with unexplained heart block and potential exposure to ticks in an endemic area. Lyme disease is diagnosed by identification of the spirochete with serologic testing. Silver staining of endomyocardial biopsy also identifies the spirochete. A screening ECG should be performed whenever the diagnosis of Lyme disease is suspected.

Atropine or isoproterenol may be used to treat first-degree or second-degree heart block or third-degree block that is...
hemodynamically stable. Temporary placement of a pacemaker is often required in unstable patients. Antibiotic therapy with intravenous penicillin or oral tetracycline is effective and can reverse atrioventricular block. Erythromycin should be prescribed in place of tetracycline in young children. Ceftriaxone is also effective. The role of antibiotics in preventing Lyme disease–related carditis is unknown.

### ACQUIRED IMMUNODEFICIENCY SYNDROME–RELATED MYOCARDIAL DISEASE

#### Epidemiology

The cardiac manifestations of AIDS are diverse and cause death in at least 6% of patients with HIV (HIV is discussed in Chapter 130). The prevalence of left ventricular dysfunction in adult AIDS patients is approximately 20%. Myocarditis is described in approximately 46% of AIDS patients undergoing postmortem examination. Most AIDS patients exhibit cardiac involvement as their underlying disease worsens.

#### Etiology

The pathogenesis of HIV-related heart muscle disease is multifactorial. The direct etiologic role of HIV infection in cardiomyopathy is controversial. Cytomegalovirus infection is a major cause of morbidity in AIDS and can cause myocarditis, as can infection with Toxoplasma. Of AIDS patients with toxoplasmosis, 28% initially have cardiac symptoms, such as cardiomegaly, CHF, dysrhythmias, pericarditis, pericardial tamponade, or chest pain. Mycobacterium tuberculosis, Aspergillus fumigatus, coxsackie B virus, cryptococcal, and Histoplasma myocarditis also occur.

HIV disease treatment may also lead to cardiac toxicity. Pentamidine, which is structurally similar to procainamide, can cause torsades de pointes ventricular tachycardia. Zidovudine and dideoxyinosine also can lead to cardiac dysfunction.

### OTHER CAUSES OF MYOCARDITIS

Cardiac involvement with Legionella pneumophila is uncommon, although the heart may be the only affected organ. Clinical symptoms resemble pericarditis and myocarditis, including dysrhythmias and conduction blocks. After treatment with erythromycin, normal cardiac function may return.

Cardiac Toxoplasma infection may lead to clinically significant disease. Infection is well described in recipients of bone marrow and cardiac transplantation. Immunocompromised patients with toxoplastic myocarditis may have bundle branch block, CHF, pericarditis, and dysrhythmias as a result of lesions in the conducting system. Untreated toxoplastic myocarditis is fatal.

Myocarditis associated with M. pneumoniae may be caused by direct invasion of the myocardium, an autoimmune mechanism, or intravascular coagulation. Miliary tuberculosis, including tuberculosis myocarditis, can produce granulomas within the myocardial conduction system that can precipitate fatal dysrhythmias. Sudden death can also occur secondary to Chlamydia pneumoniae myocarditis. In addition, myocarditis, presumably mediated by exotoxin, is associated with Shigella infection.

Cardiac involvement of the conduction system and the pericardium also may occur in dermatomyositis and polymyositis. Patients are usually asymptomatic, but pericarditis, myocarditis, and dysrhythmias can occur.

### PHARMACOLOGIC CARDIOTOXICITY

Cocaine has various cardiac effects in addition to ischemia, including myocarditis and DCM. Myocarditis is a common autopsy finding in patients with cocaine abuse. The mechanism responsible for the cardiotoxic effects of cocaine is largely unknown. Theories include the following: (1) cocaine may have a direct effect on lymphocyte activity; (2) intravenous cocaine can increase natural killer cell activity in blood, which may be cytotoxic to myocardial cells; (3) there is a cocaine-related eosinophilic infiltrate that suggests a hypersensitivity reaction; and (4) catecholamine administration can induce a focal myocarditis. Cocaine has a direct, negative inotropic effect on cardiac muscle.

Patients who die with detectable cocaine levels have myocarditis and myocardial contraction bands more often than controls. The severity of contraction-band necrosis correlates with the serum and urine concentrations of cocaine. Catecholamine excess caused by cocaine use may contribute to contraction-band necrosis, which may supply the anatomic substrate for ventricular dysrhythmias.

Lastly, acute and chronic cardiotoxicity occur secondary to the use of doxorubicin. Manifestations of acute cardiotoxicity include dysrhythmias, pericarditis, myocarditis, and left ventricular dysfunction.

### KAWASAKI DISEASE

Kawasaki disease, or mucocutaneous lymph node syndrome, is of unknown etiology and primarily affects children. This self-limited vasculitis affects many organ systems. Twenty-five percent of all patients develop coronary artery abnormalities, usually several weeks after symptom onset. These are usually reversible but may lead to aneurysm formation or secondary thrombosis and myocardial ischemia. Myocarditis and pericarditis also occur during the initial phase of the disease.

### CARDIOMYOPATHIES AND SPECIFIC HEART MUSCLE DISEASE

Cardiomyopathies are a heterogeneous group of diseases associated with mechanical or electrical dysfunction that usually exhibit inappropriate ventricular hypertrophy or dilatation and are due to a variety of causes that are frequently genetic. The diseases include are genetic (hypertrophic cardiomyopathy, arrhythmogenic right ventricular cardiomyopathy, mitochondrial myopathies, and ion channel disorders), mixed (dilated cardiomyopathy and restrictive cardiomyopathy), and acquired (inflammatory, stress provoked or tako-tsubo, peripartum, and tachycardia induced).

A variety of pathologic processes may initiate myocyte injury. When a threshold of injury occurs, common pathophysiologic pathways are activated. These pathways involve neurohumoral factors, immune factors, and cytokines. These factors contribute to myocyte dysfunction, which leads to remodeling. In response to disease, the heart remodels usually by hypertrophy or dilatation. There is also an increase in interstitial fibrosis, which impairs ventricular filling; this leads to increased metabolic demands on the myocardium. The ultimate pathophysiologic derangement may be the troponin complex, intracellular concentration of calcium, myocardial subproteins, or the sarcomere. These lesions lead to alteration in the cardiac muscle’s ability to contract, which eventually leads to clinical pathology. There is also change in the cardiac microvascular circulation that is an independent predictor of morbidity and mortality.
The traditional splitting of cardiomyopathies into subtypes may evolve into a unified theory that shows all types of cardiomyopathy to be variations of a common genetic, anatomic, and humoral pathophysiological process.

Mutations of genes for myocardial protein components lead to molecular changes in heart muscle that lead to clinical cardiomyopathy. The correlation between genotype, phenotype, and clinical presentation is unknown when the molecular level changes transition from compensatory to pathologic.

**DILATED CARDIOMYOPATHY**

**Epidemiology and Etiology**

DCM is a spectrum of disorders that have in common a dilated and failing heart for which no cause can be established. The incidence of DCM is estimated to be 36 cases per 100,000 persons per year. The true incidence is probably underestimated because many asymptomatic cases remain undiagnosed. DCM is estimated to affect 5.5 million adults and 500,000 children in the United States, costing $10 billion. It is estimated that 50% of cases previously thought to be of unknown etiology may be secondary to infection. Myocarditis is the most common cause of DCM in children.

DCM affects men more often than women, affects African Americans more than whites, and may occur in any age group, with middle age (40–65 years old) being the most common. Risk factors include ethanol and tobacco abuse, pregnancy, hypertension, and infection. Among patients with DCM, approximately 25% have an inherited form.

**Pathophysiology**

There are both primary and secondary etiologies for DCM. Possible pathophysiologic causes include myocardial inflammation mediated by cytokines, macrophages, and natural killer cells; local inflammation caused by the release of cytokines by infiltrating lymphocytes; direct reaction of antibodies with receptors on myocardial muscle; toxins, such as ethanol, impairing myocardial biochemical processes; and loss or dysfunction of myocardial matrix proteins. Myocardial damage initiates a vicious cycle of hypertrophic cell death that increases the burden of the remaining cells; this leads to signaling, more work, and cell death.

Identification of a genetic basis for the coxsackievirus adenovirus receptor and efforts to correlate this with cases of DCM suggest that development of a vaccine against coxsackievirus and adenovirus may decrease these infections in myocarditis and DCM.

**Clinical Features**

Symptoms of DCM have an insidious onset. Left-sided heart failure occurs as the initial manifestation in 75% of adults, with dyspnea (usually with exertion or while supine) the major symptom. Exacerbation of heart or renal disease, dietary indiscretion, and medication noncompliance are key contributors. CHF symptoms are the most common presentation in children. Chest pain on exertion is the initial symptom in 10% of adults, and systemic or pulmonary emboli are the initial manifestation in 4%. Right-sided heart failure is a late and ominous sign.

**Diagnostic Strategies**

ECG findings are nonspecific and may include poor R wave progression, intraventricular conduction delay, or left bundle branch block pattern. Holter monitoring may show frequent premature ventricular contractions and occasional ventricular tachycardia. Sudden death is uncommon. The chest radiograph reveals cardiomegaly.

Echocardiography shows left ventricular dilation, reduced systolic function, and variable wall motion abnormalities. Abnormal ventricular contractility defines DCM, and an ejection fraction less than 45% is required for diagnosis. End-diastolic and systolic volumes are increased, as are pulmonary capillary wedge pressure and central venous pressure.

Endomyocardial biopsy may also be necessary. Histologic abnormalities are nonspecific. New histochemical, immunologic, and molecular biologic techniques improve the diagnostic yield, especially for infectious causes.

**Management and Disposition**

Therapy includes supportive measures, such as adequate rest, weight control, abstaining from tobacco, moderate salt and ethanol consumption, and reduced physical activity. Medical treatment includes standard measures for CHF.

Angiotensin-converting enzyme inhibitors reduce morbidity and mortality. Other afterload-reducing agents, such as isosorbide dinitrate and hydralazine, also prolong survival in patients with heart failure. Spironolactone and the angiotensin receptor-blocking agents also prolong survival. Implantable defibrillators improve survival and short-term statin therapy may help. Antidysrhythmics are not usually effective.

Various beta-blockers can reduce symptoms and improve left ventricular function, functional capacity, and survival. In addition, the improvement in cardiac function associated with beta-blockers is also associated with changes in expression of genes encoding for α- and β-myosin heavy-chain and sarcoplasmic reticulum calcium adenosine triphosphate.

**Outcome**

Since medical therapy usually fails, DCM is the leading indication for cardiac transplantation in adults and children. Mortality from DCM is 18% by 1 year, 35% by 5 years, and 50% by 10 years. Patients with DCM show progressive deterioration, with 75% of patients dying within 5 years of diagnosis.

The clinical course for children is variable, with a better prognosis in young children. Most deaths occur within the first 2 years. Some children show delayed, spontaneous, and unexplained improvement.

**HYPERTROPHIC CARDIOMYOPATHY**

**Perspective**

Hypertrophic cardiomyopathy (HCM) is a complex disorder with variable clinical manifestations. The prevalence is estimated to be 1 in 500 persons in the general population. It affects all races, men and women equally, and can present at any age.

**Principles of Disease**

**Anatomy**

HCM is a disease involving abnormalities of heart muscle at anatomic, cellular, and genetic levels. The defining anatomic feature of HCM is a hypertrophied left ventricle in the absence of another cause of left ventricular hypertrophy. The thickening is usually asymmetrical and involves the septum more than the free ventricular wall. The extent of hypertrophy at any
given site can vary greatly and bears significantly on the manifest-
ization of the disease. The dimensions of the left ventricular 
and right ventricular cavities are small or normal. Atrial dilation 
is another feature.

Histologically, individual muscle cells are hypertrophied, 
with a disorganized, characteristic whorled pattern.\textsuperscript{41} Sarco-
mere disarray is the histologic hallmark. Abnormal fibrous 
tissue is often found in the left ventricle, and the scarring mimics a healed MI.

**Pathophysiology**

HCM is an autosomal dominant disease caused by mutations 
in genes that encode for sarcomere contractile proteins. Ten 
genes encoding for cardiac sarcomere proteins and more than 
200 different mutations of these genes are identified. Half the 
mutations involve three genes: those for $\beta$-myosin heavy chain 
(which constitutes 30% of myocardial protein), myosin-binding 
protein C, and troponin-T.\textsuperscript{46}

$\beta$-Myosin heavy chain is a contractile protein with enzyme 
activity responsible for hydrolyzing adenosine triphosphate. 
Troponin-T constitutes approximately 5% of the total myo-
fibrillar protein and is involved in regulation of calcium. A 
decreased quantity of stable cardiac troponin-T alters the stoi-
chiometry of the sarcomere.

Genetic studies of families with HCM identify specific 
mutations that correlate with sudden cardiac death. In families 
with Arg403Gln mutation, less than half of affected family 
members survive past 45 years of age. Genetics alone does not 
account for the clinical manifestation of HCM, since patients 
with the same genotype differ in phenotypic expression and 
clinical course. This indicates that modifier genes and envi-
ronmental factors are also important.

The hypertrophy in HCM may be a compensatory response 
to the cardiac protein abnormalities. In vitro studies show that 
mutant $\beta$-myosin heavy chain protein exhibits impaired con-
tractility and disrupts formation of the normal sarcomere. The 
usual cardiac response to physiologic stress is hypertrophy, 
dilation, or a combination of both. A gene mutation may lead 
to mutant protein that impairs cellular structure and function 
due to fibrous changes in the sarcomere. This causes compen-
satory tissue hypertrophy that is manifest as HCM.

Clinically, patients with HCM have asymmetric left ven-
tricular hypertrophy. They have an abnormal echocardiogram 
or cardiac magnetic resonance image that shows hyperdynamic 
ventricles. There may be an outflow obstruction, although this 
usually occurs with exertion. The thickness of the ventricle 
and degree of outflow obstruction correlate with disease sever-
ity. The pathophysiology involves impaired ventricular filling 
during diastole.

**Clinical Features**

HCM occurs at all ages. The average age at diagnosis is 30 to 
40 years. Approximately 2\% of cases are diagnosed in children 
younger than age 5 years, and 7\% are diagnosed before 10 
years of age. HCM gained notoriety after the sudden deaths 
of several young athletes and the attendant press coverage. 
There is advocacy for large-scale ECG screening of young 
athletes, but no studies demonstrate an appropriate strategy 
for effective screening for the condition. The presentation of 
HCM varies widely. HCM may be discovered by screening 
relatives of patients who have HCM.\textsuperscript{41}

In many patients, the initial event is sudden death, which 
usually occurs during exertion. Ninety percent of patients 
have shortness of breath. Other symptoms include chest pain, 
syncope, near-syncope, and palpitations.

Physical examination may reveal a loud S\textsubscript{4} gallop and a harsh 
crescendo-decrescendo middysystolic murmur. This murmur is 
accentuated by the Valsalva maneuver or standing/squatting. 
Such position interventions change preload and afterload, 
which accentuates the murmur. Other physical findings may 
include a bifid arterial pulse, paradoxical splitting of the second 
heart sound, and, rarely, a mitral leaflet septal contact sound. 
Many dysrhythmias are seen in HCM, including premature 
atrial and ventricular contractions, multifocal ventricular 
ectopy, and ventricular and supraventricular tachydysrhyth-
mas. In the ED, the diagnosis should be suspected in anyone 
with a family history, characteristic murmur, and cardiopulmo-
nary symptoms (i.e., chest pain, dyspnea, and dysrhythmia) 
not explained by other life-threatening conditions.

**Diagnostic Strategies**

Patients with suspected HCM should have an ECG, chest 
radiograph, and echocardiogram. The ECG is abnormal in 
approximately 90\% of patients. The most common abnormali-
 ties are left ventricular hypertrophy, ST segment alterations, 
T wave inversion, left atrial enlargement, abnormal Q waves, 
and diminished or absent R waves in the lateral leads. The 
chest radiograph may be normal or show left ventricular or 
atrial enlargement.

Echocardiography is the most important diagnostic strategy. 
Findings include asymmetrical left ventricular hypertrophy, 
left ventricular outflow tract narrowing, a small left ventricular 
cavity, and reduced septal motion. The dynamic characteristic 
of HCM distinguishes it from the discrete forms of obstruction 
to ventricular flow. Doppler techniques help assess the 
severity of this obstruction at rest and with provocative 
maneuvers.

Magnetic resonance is helpful when the echocardiogram is 
not. Nuclear studies can be used to assess systolic and diastolic 
ventricular function and ventricular scarring. Electrophysio-
logic studies may show dysrhythmias but are not more predic-
tive of sudden death than clinical factors.\textsuperscript{42} Genetic screening 
may be helpful to predict other family members at risk.

**Differential Diagnosis**

HCM mimics many disorders. In individuals who have a gradi-
ent and a loud systolic murmur, HCM may be confused with 
valvular diseases or ventricular septal defect. In the absence 
of a murmur, symptoms may suggest mitral valve prolapse, 
primary pulmonary hypertension, or coronary artery disease. 
ECG changes, without a history of preceding MI, may also 
suggest HCM. Echocardiography is often helpful, but ulti-
mately cardiac catheterization may be necessary to confirm the 
diagnosis.

**Management**

Beta-blockers are the mainstay of therapy. They decrease the 
effect of catecholamines on the outflow gradient. This pro-
longs diastole, increases ventricular filling, and results in 
symptomatic improvement (primarily dyspnea and chest pain) 
and exercise tolerance.\textsuperscript{43} Calcium channel blockers are also 
useful. Verapamil reduces obstruction, decreases contractility, 
and improves diastolic relaxation and filling. This improves 
exercise capacity, and the negative effects on heart rate and 
blood pressure decrease oxygen consumption and the inci-
dence of angina. Verapamil is contraindicated when conduc-
tion blocks are present, but it should be considered when 
there is no response to beta-blockers. Another option is 
disopyramide.
Nitroglycerin, the traditional initial ED management for chest pain, is not indicated in HCM-associated chest pain because it decreases ventricular volume. Amiodarone is the drug of choice for treatment of ventricular dysrhythmias in HCM. Amiodarone may also control atrial fibrillation. Automatic implantable cardioverter defibrillators are indicated for patients with sudden death or a history of a sudden death risk factor. It is probably not necessary to give prophylactic antibiotics in patients with HCM.

Surgical treatment is reserved for patients with large (>50 mm Hg) systolic gradients, severe symptoms, and poor quality of life who do not respond to drug therapy. The most common procedure is septal myomectomy. Dual-chamber pacing decreases outflow gradient and improves symptoms, but it does not improve outcome.

**Disposition**

The natural history of HCM is variable and probably reflects the many different genetic etiologies. The annual mortality rate is 1%.

The onset of atrial fibrillation in patients with HCM may precipitate marked hemodynamic compromise and severe CHF. Cardioversion is indicated, as is rate control and anticoagulation to prevent thromboembolism.

Risk factors for sudden death include malignant genotype, unexplained syncope, sudden death in first-degree relatives, abnormal hemodynamic response to exercise, and greater than 30-mm ventricular thickening.

Patients with HCM initially diagnosed in the ED should have strenuous physical activity specifically proscribed until evaluated by a cardiologist. Patients with HCM who have angina, syncope, near-syncope, dysrhythmias, and abrupt changes in cardiopulmonary status should be hospitalized.

**RESTRICTIVE CARDIOMYOPATHY**

**Perspective**

The hallmark of RCM is a gradual and progressive limitation of ventricular filling secondary to myocardial infiltration. RCM is the least common type of cardiomyopathy. The most common etiology is amyloidosis. Other etiologies include sarcoidosis, hemochromatosis, scleroderma, neoplastic cardiac infiltration, radiation heart disease, glycogen storage disorders, Fabry’s disease, and Gaucher’s disease.

The most common cause of RCM worldwide is tropical endomyocardial fibrosis, which is endemic to India, Africa, and Latin America. Symptoms include an initial viral-like illness followed by persistent fever, malaise, and the development of severe right-sided heart failure.

**Principles of Disease**

Restriction of ventricular filling results in low ventricular volumes, high end-diastolic ventricular pressures, and decreased cardiac output. Systolic function is maintained. Grossly, there is atrial enlargement with small ventricles. As the disease progresses, the ventricular cavities may become obliterated by fibrous tissue, scarring, or thrombus.

**Clinical Features and Diagnostic Strategies**

Symptoms are those of worsening diastolic dysfunction and include exercise intolerance (cardiac output cannot be increased because ventricular filling is compromised), elevated central venous pressure, peripheral edema, pulmonary edema, and S3 and S4 gallops on auscultation. Children can present with failure to thrive.

Differentiation from constrictive pericarditis requires CT, MRI, or Doppler echocardiography. Pericardial calcification favors a diagnosis of constrictive pericarditis over the diagnosis of RCM. Myocardial biopsy may be necessary.

**Management and Disposition**

Most of the underlying causes of RCM are untreatable. The exception is hemochromatosis. Symptomatic treatment with vasodilators and diuretics may help. Patients with RCM should be maintained in sinus rhythm, since loss of the “atrial kick” is devastating. Transplantation is a possibility in some patients. RCM is relentless, with 90% of patients dying within 10 years of diagnosis.

**PERIPARTUM CARDIOMYOPATHY**

**Perspective**

Peripartum cardiomyopathy (PPCM) is uncommon. It represents less than 1% of the cardiovascular problems associated with pregnancy. PPCM is a form of DCM with symptoms and signs of heart failure that present initially during the last 3 months of pregnancy or the first 5 months postpartum.

**Etiology and Epidemiology**

The etiology of PPCM is unknown. Proposed etiologies include myocarditis, excessive use of tocolytics, preeclampsia, altered autoimmune response, selenium or nutritional disorders, or genetic predisposition. The incidence is estimated to be 1 case of PPCM per 3000 live births in the United States and is higher in other countries. It is more common in women who are older than age 29 years or African American.

**Clinical Features and Diagnostic Strategies**

PPCM is clinically identical to DCM. Patients usually have symptoms of CHF but may also have chest pain, palpitations, or thromboembolism. Physical examination often reveals tachycardia, tachypnea, pulmonary rales, an enlarged heart, and an S3 heart sound.

The ECG may show left ventricular hypertrophy or non-specific ST-T wave changes. On echocardiography, all four chambers are enlarged with reduction in left ventricular systolic function.

**Management and Disposition**

Treatment of PPCM includes limitation of physical activity, beta-blockers, alteration of preload with nitrates and diuretics, increase in ventricular contractility, and afterload reduction.

Angiotensin-converting enzyme inhibitors are teratogenic and should be avoided, if possible, in pregnancy. Hydralazine and labetalol are effective and a good choice for treating PPCM in the ED.

Mortality for PPCM in the United States is approximately 2%. Half of the survivors have complete or near-complete recovery of cardiac function within the first 6 months. Patients who do not recover completely show either continuous clinical deterioration or persistent left ventricular dysfunction. Subsequent pregnancies may be associated with a high risk of maternal mortality. In the ED, patients with signs of hemodynamic instability or failure to maintain oxygenation should be admitted for treatment and fetal monitoring.
ION CHANNELopathies

Several uncommon dysrhythmic diseases are caused by mutations of genes for ionic channel proteins, which are cell membrane transport proteins for sodium and potassium. These include long QT syndrome, short QT syndrome, Brugada’s syndrome, and catecholaminergic polymorphic ventricular tachycardia.40

SPECIFIC HEART MUSCLE DISEASES

Amyloidosis

Disorders of amyloid deposition are divided into two categories: primary amyloidosis (associated with a high incidence of cardiac involvement) and amyloidosis secondary to multiple myeloma, RA, tuberculosis, or lymphoma. In cardiac amyloidosis, the cells of the reticuloendothelial system are stimulated to deposit amorphous material in the ventricle, coronary arteries, or valves. Massive amyloid deposition results in an increased cardiac weight and the diastolic dysfunction of RCM. CHF occurs in most cases of cardiac amyloidosis. Treatment involves standard CHF and antidysrhythmic therapy, although the dysrhythmias in amyloid heart disease are often refractory to treatment. The prognosis is poor, with death often resulting from progressive heart failure within 1 year of symptom onset.49

Sarcoidosis

Cardiac granulomas occur in approximately 25% of cases of systemic sarcoidosis. Granulomas located in the septum cause severe conduction defects, those in the papillary muscles cause mitral regurgitation, and those in the ventricular walls produce scarring and wall motion abnormalities. Complete heart block is the most common conduction block. Ventricular dysrhythmias are often refractory to therapy. Myocardial involvement in sarcoidosis is an indication for systemic corticosteroid therapy. Refractory cardiac failure and dysrhythmias are indications for heart transplantation.

Connective Tissue Disorders and Disease of the Myocardium

Myocarditis associated with various connective tissue diseases occurs more often than is recognized clinically. Cardiac abnormalities occur in RA, juvenile RA, mixed connective tissue disease, and primary Sjögren’s syndrome. SLE is the connective tissue disease most commonly associated with cardiac abnormalities. Cardiac involvement in SLE includes pericarditis, endocarditis, and myocarditis.

Primary myocardial involvement is a major complication of diffuse scleroderma and develops as scleroderma worsens. Estimates of the frequency of myocardial involvement in scleroderma vary widely. The clinical presentation includes CHF, angina, and dysrhythmias. Pericardial disease can also occur. Although prognosis is poor, azathioprine may be a beneficial adjunct to steroid therapy.50

Sudden Death

Approximately 25% of sudden deaths in patients younger than age 21 years can be attributed to disease of the myocardium. Cardiac etiologies include myocarditis, HCM, and anomalous coronary artery circulation. In patients with sudden death attributed to cardiac etiologies, prodromal symptoms are reported in more than half of the patients, most commonly chest pain (25%) in patients older than age 20 years and dizziness (16%) in patients younger than age 20 years. The distribution of sudden death etiologies by age is as follows:

- Age younger than 20 years—myocarditis 22% and HCM 22%
- Age 20 to 29 years—myocarditis 22% and HCM 13%
- Age 30 to 39 years—myocarditis 11% and HCM 2%

Coronary artery disease becomes the leading cardiac etiology (58%) in sudden death in people ages 30 to 39 years. HCM is the cardiac disease most commonly found on postmortem diagnosis of athletes with sudden death. HCM and anomalous coronary arteries are seen more often in sports-related deaths.

KEY CONCEPTS

- Pericarditis must be differentiated from acute MI. Thrombolytic therapy is contraindicated in pericarditis because of the potential for hemorrhagic pericarditis or tamponade.
- Cardiac tamponade must be suspected (distended neck veins, hypotension, and muffled heart sounds), diagnosed (echocardiography), and treated (pericardiocentesis) quickly. Pericardiocentesis may be diagnostic and therapeautic.
- Myocarditis should be considered in any patient with the combination of viral illness symptoms and signs of cardiac disease.
- The symptoms and signs of constrictive pericarditis are virtually indistinguishable from those of RCM.
- Patients with newly diagnosed hypertrophic cardiomyopathy should avoid strenuous exertion until evaluated by a cardiologist. Beta-blockers are the mainstay of therapy for HCM; avoid nitrates.

Chapter 81 Infective Endocarditis and Valvular Heart Disease

Joshua M. Kosowsky

INFECTIVE ENDOCARDITIS

Perspective

The term infective endocarditis (IE) has replaced the older classifications of acute, subacute, and chronic as they have become less meaningful in the antibiotic era. Although bacteria remain the most common etiology, virtually all organisms (including viruses, fungi, and rickettsiae) can cause endocarditis. Early diagnosis of endocarditis and treatment of the causative organism play a significant role in the clinical outcome.

Principles of Disease

Estimates of the incidence of IE in the United States vary widely, in part because of changing case definitions throughout the years but also because of differences in predisposing conditions among studied populations. For example, the incidence of IE among patients admitted to hospitals in Philadelphia was estimated to be 11.6 cases per 100,000 person-years from 1988 to 1990. In contrast, the incidence of endocarditis in Olmsted County, Minnesota, during the period from 1970 to 2000 was 5.0 to 7.0 cases per 100,000 person-years. Others report significantly lower rates. IE is increasingly a disease of the aged, with more than 50% of cases occurring in individuals older than age 60 years. This reflects the pervasiveness of degenerative valve disease in the elderly and the increased prevalence of prosthetic heart valves.

Most patients with bacterial endocarditis have a predisposing valvular abnormality. Among elderly patients, calcific or degenerative disease of the aortic and the mitral valve is the most common predisposing factor. Rheumatic heart disease, although less prevalent than in prior decades, remains an important predisposing factor for IE among individuals from developing countries. Congenital cardiac lesions involving high-pressure gradients (e.g., ventricular septal defects, pulmonary stenosis, and tetralogy of Fallot) also increase risk for IE. A history of previous endocarditis is a major risk factor for recurrence because infected valves heal with irregularities that become a nidus for future vegetations.

The incidence of IE associated with injection drug use is estimated at 150 to 200 per 100,000 person-years. Although any valve can be affected, injection drug use is classically associated with right-sided endocarditis.

Prosthetic valve endocarditis is a unique and potentially devastating complication of valve replacement. The incidence of endocarditis in prosthetic valve recipients ranges from 0.5 to 4% per year. Prosthetic valve endocarditis can arise early or late after surgery, and the timing of infection reflects different epidemiology and microbiology.

The 5-year mortality rate for native valve endocarditis is 20%, but in the presence of a prosthetic valve estimates range up to 60%. The mortality for right-sided endocarditis in a patient with a history of injection drug use is approximately 10%.

Pathophysiology

The classic lesion of endocarditis is the vegetation, originating as a sterile thrombus upon which microorganisms adhere and colonize. The initial thrombus may form at a site of mechanical damage induced by inflammation, degenerative changes, or abnormal turbulence. In injection drug users, contaminants such as talc can injure the previously normal valve leaflets and encourage bacterial implantation. Theoretically, the onset of bacterial endocarditis is preceded by a period of subclinical bacteremia. Dental procedures, cystoscopy, endoscopy, and other invasive procedures result in transient bacteremia, but more commonly there is no clear precipitant for community-acquired IE.

A number of microorganisms cause IE, with staphylococci and streptococci accounting for the majority of cases (Table 81-1). In a study of nearly 1800 patients with IE from 39 medical centers in 16 countries, staphylococci were the etiologic agents in 42% (commonly associated with injection drug use) and streptococci in 40%.

The microbiology of prosthetic valve endocarditis relates to the time of onset: Staphylococcus aureus is by far the most prevalent pathogen in the first two months following valve replacement. Subsequently, the microbiology mirrors native valve endocarditis.

Among injection drug users, the most common infecting organism by far is S. aureus, particularly in right-sided infections.

The HACEK group (Haemophilus aphrophilus, Actinobacillus actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens, and Kingella kingae) are fastidious gram-negative bacilli that are difficult to isolate. Bartonella species are another group of fastidious organisms associated with IE immunocompromised patients.

Candida and Aspergillus species cause most cases of fungal endocarditis. Predisposing factors include indwelling IV catheters, immunocompromise, and injection drug use. Large
fungal vegetations can embolize, and histologic analysis of these emboli may be the only clue suggesting fungal endocarditis.

Clinical Features
Symptoms associated with IE are nonspecific and diverse. The most common symptoms are intermittent fever (85%) and malaise (80%). Other symptoms (e.g., weakness, myalgias, back pain, dyspnea, chest pain, cough, headaches, and anorexia) vary widely in their incidence and are also nonspecific. Many patients who present early during the bacteremic phase of the illness do not have a cardiac murmur and are indistinguishable from the large population of patients who present to the emergency department (ED) with a febrile viral illness. During the initial assessment, a careful history should be performed with attention to any preexisting cardiac pathology or clues suggesting a recent source of bacteremia, such as intravenous drug use, indwelling intravascular catheters, or invasive procedures. In the absence of specific risks, the diagnosis of IE may be suspected when infectious symptoms persist or do not follow a typical course for viremia. The classic triad of fever, anemia, and heart murmur is rare.

Almost all patients with IE have a cardiac murmur at some time during the course of their illness. A murmur, however, may be absent at presentation. For example, fewer than 35% of IV drug users with endocarditis present with a murmur. In this population, unexplained fever alone is sufficient to raise concern about possible endocarditis. A substantial minority of patients exhibit some form of vasculitic lesion, including petechiae, splinter hemorrhages, Osler’s nodes, and Janeway lesions. Approximately 50% of patients have splenomegaly. Ocular findings include conjunctival or retinal hemorrhages, the latter of which may have a characteristic pale center surrounded by a red halo (Roth’s spots).

Diagnostic Strategies
Laboratory findings in bacterial endocarditis are nonspecific. Similar to other infectious conditions, leukocytosis is insensitive (occurring in approximately 50% of patients diagnosed with IE) and nonspecific. An elevated erythrocyte sedimentation rate or C-reactive protein may be present, but these are also nonspecific. Most patients have a mild anemia, and up to 50% have microscopic hematuria as a result of embolic lesions of the kidney. A chest radiograph may show signs of heart failure, and an electrocardiogram (ECG) may display conduction abnormalities if an abscess has formed in the myocardium.

Three blood cultures from three separate venipuncture sites should be obtained for all patients with a presumptive diagnosis of possible endocarditis, with the first and last culture drawn at least 1 hour apart. Approximately 90 to 95% of blood cultures are positive unless antibiotics have already been administered. If the patient appears septic, cultures may be obtained more rapidly to permit initiation of early empiric therapy. Cultures need not be timed to the presence of chills or fever because patients with IE typically have a continuous bacteremia.

An echocardiogram should be performed in all patients with a moderate to high suspicion of endocarditis. Although trans-thoracic echocardiography (TTE) is highly specific for vegetations in IE, it may be nondiagnostic in up to 20% of patients because of obesity, chronic obstructive pulmonary disease, and chest wall deformities. Overall sensitivity of TTE is at most 60%. Transesophageal echocardiography (TEE), on the other hand, although more invasive and time-consuming, is far superior to TTE in its sensitivity. The negative predictive value for IE with a normal TEE without prosthetic valves approaches 100%.

Explicit criteria for the diagnosis of IE are important since underdiagnosis can lead to serious morbidity and death, whereas overdiagnosis can result in weeks of unnecessary antimicrobial therapy. The Duke criteria are the most widely accepted, and they stratify patients with suspected bacterial endocarditis into three distinct categories: definite, possible, and rejected (Box 81-1). The sensitivity and specificity of the Duke criteria are approximately 95% and 99%, respectively.

Management
Once the diagnosis of IE is established, whether by clinical, echocardiographic, or microbiologic methods, antimicrobial therapy should be administered. Choice of antibiotics depends on the likely (or known) causative organism but is usually empiric. Guidelines for empirical antibiotic therapy in patients with suspected IE are provided in Box 81-2. Febrile patients with suspected IE require admission for definitive diagnosis and initiation of empirical therapy. An exception might be an otherwise well-appearing injection drug user with transient fever that is attributed to an injected contaminant (“cotton fever”).

Consultation with an infectious diseases specialist or a cardiologist may be useful. Also, early consultation with a cardiac surgeon should be obtained for all cases in which mechanical complications are observed or expected (such as in infections involving prosthetic valves).

With appropriate antibiotic therapy, most patients with IE will defervesce within 1 week. The duration of antibiotic therapy must be sufficient to eradicate microorganisms present within the valvular vegetations. This may require up to 6 weeks, depending on the organism and the type of vegetation. Historically, most patients with IE received the entire antimicrobial therapy while in the hospital. The development of home health care, however, has allowed selected patients with endocarditis to be treated as outpatients during much or all of their therapy. Patients selected for outpatient therapy should be hemodynamically stable, compliant, and capable of managing the technical aspects of IV therapy.

DUKE CRITERIA (CLINICAL) FOR DIAGNOSIS OF INFECTIVE ENDOCARDITIS

Definite Endocarditis
Endocarditis is considered definitely present if any one of the following combinations of clinical findings is present:
- Two major clinical criteria
- One major and any three minor clinical criteria
- Five minor clinical criteria

Possible Endocarditis
Possible endocarditis is defined as the presence of any one of the following combinations of clinical findings:
- One major and one or two minor clinical criteria
- Three minor clinical criteria

Rejected Endocarditis
The diagnosis of endocarditis is considered rejected if any of the following are present:
- A firm alternate diagnosis is made
- Resolution of clinical manifestations occurs after 4 days of antibiotic therapy or less
- Clinical criteria for possible or definite infective endocarditis not met

Major Criteria
Positive blood cultures (of typical pathogens) from at least two separate cultures
Evidence of endocardial involvement by echocardiography, such as the following:
- Endocardial vegetation
- Paravalvular abscess
- New partial dehiscence of prosthetic valve
- New valvular regurgitation

Minor Criteria
Predisposition: Predisposing heart condition or IV drug use
Fever: ≥38°C
Vascular phenomena: Arterial emboli, septic pulmonary infarcts, mycotic aneurysm, conjunctival hemorrhages, or Janeway lesions
Immunologic phenomena: Osler’s nodes, Roth’s spots, and rheumatoid factor
Microbiologic evidence: Single positive blood culture (except for coagulase-negative Staphylococcus or an organism that does not cause endocarditis)
Echocardiogram findings: Consistent with endocarditis but do not meet major criteria

INITIAL EMPirical THERAPy FOR BACTERIAL ENDOCARDITIS

Native Valve
Penicillin G 5 million units IV q 4 hr + nafcillin 2 g IV q 4 hr
Or
Vancomycin 15 mg/kg IV q 12 hr
Plus
Gentamicin 1 mg/kg IV q 8 hr

Native Valve (+ Injection Drug Use)
Vancomycin 15 mg/kg IV q 12 hr

Prosthetic Valve
Vancomycin 15 mg/kg IV q 12 hr
Plus
Gentamicin 1 mg/kg IV q 8 hr

Prophylaxis
The American Heart Association has updated guidelines, limiting prophylaxis to conditions with the highest risk of adverse outcome from IE (Box 81-3).23 Virtually all of the procedures that are routinely performed in the ED, including suturing of lacerations, endotracheal intubation, placement of central venous catheters, vaginal deliveries, and placement of Foley catheters (in the absence of infection), do not require prophylactic antibiotics.

RHEUMATIC FEVER

Perspective
From 1920 to 1950, acute rheumatic fever (ARF) was the leading cause of death in U.S. children and the most common cause of heart disease in individuals younger than age 40 years. During the 1960s and 1970s, the incidence of ARF in the United States and other developed countries declined dramatically because of widespread antibiotic treatment of streptococcal infections, declining prevalence of the more virulent strains of group A streptococci, and improved living conditions. Children between 4 and 9 years of age remain at greatest risk, with an incidence of ARF between 2 and 14 cases per 100,000.24 In many developing nations, however, ARF continues to be a leading cause of childhood mortality.

Principles of Disease
ARF is a delayed, nonsuppurative complication of streptococcal pharyngitis. Although the pathogenesis remains obscure, ARF may result from a particular immunologic response to group A β-hemolytic streptococci that results in antibodies cross-reacting with tissues in the heart, joints, skin, and central nervous system.

Clinical Features
After the initial pharyngitis, there is a latency period ranging from 1 to 5 weeks (average, 18 days) before symptoms and signs of ARF appear. Up to one third of patients with documented ARF do not remember having pharyngitis in the preceding month. Fever is present during the acute phase of rheumatic fever. It rarely lasts more than 2 weeks and has no characteristic pattern. Along with fever, manifestations of ARF may include arthritis, carditis, chorea, subcutaneous nodules, and erythema marginatum.

Migratory polyarthritis is the most common manifestation of ARF. Arthritis tends to occur early in the course of ARF and often coincides with a rising titer of streptococcal antibodies. The polyarthritis classically affects larger joints, such as the knees, ankles, elbows, and wrists, and the pain can be more...
Cardiac manifestations of ARF may be subtle and can include symptoms and signs of pericarditis, myocardiitis, and endocarditis. The mitral valve is the most common valve affected in ARF, causing mitral regurgitation accompanied by a new, high-pitched, systolic murmur. Inflammation of the valvular endocardium can result in permanent deformity and impairment of one or more cardiac valves over the course of decades. Stenotic lesions of the mitral or aortic valves are unusual at presentation, but they are common late manifestations of rheumatic heart disease.

Chorea (Sydenham’s chorea and St. Vitus’ dance) is manifested by random, rapid, purposeless movements usually of the upper extremities and face. This can be associated with emotional outbursts. Chorea is relatively rare in ARF and tends to emerge after a longer latency period than some of the other manifestations. Erythema marginatum and subcutaneous nodules are found in fewer than 10% of cases of ARF. Their presence, however, should immediately suggest the diagnosis. Erythema marginatum is a nonpruritic, painless, evanescent “smoke ring” of erythema that commonly appears on the trunk and proximal extremities. Subcutaneous nodules are pea sized and nontender. They typically appear over the extensor surfaces of the wrists, elbows, knees, and occasionally the spine.

### Diagnostic Strategies

In 1944, Jones\(^2^5\) formulated major and minor criteria for the diagnosis of ARF. After multiple revisions, the Jones criteria remain the diagnostic basis for this disease (Box 81-4).\(^2^6\) The diagnosis of ARF requires evidence of an antecedent streptococcal infection plus at least two major, or one major and two minor, manifestations from the Jones criteria. Although throat cultures are usually negative at the time of clinical onset of ARF, antistreptolysin antibody titers remain positive for 4 to 6 weeks from the time of infection. Erythrocyte sedimentation rate and C-reactive protein levels are typically elevated, and a prolonged P-R interval is common and suggestive in ARF.

### Management

All patients with ARF should receive antibiotic therapy regardless of the clinical history of pharyngitis. Penicillin can be administered orally (250 mg for children and 500 mg for adults, two or three times daily for 10 days) or intramuscularly (600,000 U benzathine penicillin in children weighing <25 kg and 1.2 million U in adults as a one-time dose).

Treatment for arthritis consists of anti-inflammatory agents, most commonly aspirin, administered until symptoms are absent and the erythrocyte sedimentation rate and C-reactive protein concentration normalize. Patients with severe carditis are often treated with corticosteroids, but their effects show conflicting results.\(^2^7\)

Patients with ARF should receive ongoing prophylactic antibiotics (generally penicillin) to prevent recurrences. The recommended duration of secondary prophylaxis varies depending on the presence and severity of cardiac involvement.\(^2^8\)

### VALVULAR HEART DISEASE

#### Valvular Anatomy

Of the four heart valves, three (tricuspid, pulmonic, and aortic) are composed of three cusps, whereas the mitral valve has only two cusps. Each cusp is a double layer of endocardium that is attached at its base to the fibrous skeleton of the heart. The margins of the cusps are attached to muscular projections from the ventricles (papillary muscles) via tendinous chords (chordae tendineae). Contraction of the ventricle and consequently the papillary muscle results in the opening or closing of the valve depending on its location.

#### Mitral Stenosis

The most common cause of mitral stenosis is rheumatic heart disease, with the majority of patients exhibiting mitral stenosis. Symptoms of valvular dysfunction typically present after a latency period of one to three decades. Many patients will not recall a history of ARF. Less common causes of mitral stenosis include congenital mitral stenosis and mitral annular calcification.

#### Pathophysiology

The normal cross-sectional area of the mitral valve orifice is 4 to 6 cm\(^2\). Stenosis becomes clinically significant when the area falls below 2 cm\(^2\). Impeded flow from the left atrium to the left ventricle results in left atrial hypertension, restricted cardiac output, and, ultimately, pulmonary congestion. As the disease progresses, patients may develop pulmonary hypertension and right ventricular failure.

The most common complication of mitral stenosis is atrial fibrillation, which in the absence of rate control is generally not well tolerated. Patients with underlying mitral stenosis will decompensate under other conditions associated with increased cardiac demand and reduced ventricular filling, such as pregnancy, anemia, infection, and hyperthyroidism.

#### Clinical Features

Early symptoms of mitral stenosis include reduced exercise tolerance and dyspnea on exertion. Patients with more advanced disease may present with orthopnea and, if right ventricular failure is present, peripheral edema. Hemoptyis, due to rupture of a bronchial vein, and hoarseness, due to compression of the recurrent laryngeal nerve, are classic but rare presentations. Aside from the typical signs of heart failure, findings that suggest the presence of mitral stenosis include a loud S\(_2\) and an opening snap in early diastole accompanied by a low-pitched, rumbling diastolic apical murmur.

**Signs and Symptoms of ARF**

- Prolonged P-R interval is common and suggestive in ARF.
- Rate and C-reactive protein levels are typically elevated, and a 6 weeks from the time of infection.
- Erythrocyte sedimentation cultures are usually negative at the time of clinical onset of minor, manifestations from the Jones criteria. Although throat coccal infection plus at least two major, or one major and two minor, manifestations from the Jones criteria. Although throat cultures are usually negative at the time of clinical onset of ARF, antistreptolysin antibody titers remain positive for 4 to 6 weeks from the time of infection. Erythrocyte sedimentation rate and C-reactive protein levels are typically elevated, and a prolonged P-R interval is common and suggestive in ARF.
Although the chest x-ray may be normal, in more advanced cases left atrial enlargement may be suggested by straightening of the left heart border. Common ECG abnormalities in addition to atrial fibrillation include left atrial enlargement and, ultimately, right ventricular hypertrophy. Echocardiography is required to confirm the diagnosis and assess the severity of disease.

Management

Medical treatment for patients with mitral stenosis comprises diuresis for symptoms of vascular congestion and anticoagulation for atrial fibrillation. Once symptoms have developed, however, median survival without intervention is 7 years. Several surgical options exist, ranging from balloon valvulotomy or open commissurotomy to valve reconstruction or replacement. Management of the patient with mitral stenosis in the ED centers on identification and treatment of underlying precipitants such as atrial fibrillation or anemia, diuresis, and referral for definitive intervention.

Mitral Regurgitation

Acute and chronic mitral regurgitation are two distinct disease entities. Acute mitral regurgitation is a true emergency. It can result from idiopathic rupture of chordae tendineae, papillary muscle dysfunction in the setting of acute ischemia (or rupture 2–7 days postinfarction), or, rarely, perforation of a valve leaflet in the setting of infectious endocarditis or trauma. Chronic mitral regurgitation, on the other hand, most commonly occurs either in the setting of dilated cardiomyopathy (due to enlargement of the mitral annular ring) or in the setting of rheumatic heart disease. This frequently coexists with mitral stenosis. Other causes of chronic mitral regurgitation include mitral valve prolapse and connective tissue disorders, such as Marfan’s syndrome and Ehlers-Danlos syndrome.

Pathophysiology

Acute mitral regurgitation is associated with low left atrial compliance and thus sharply elevated left atrial pressure that results in acute pulmonary congestion. In contrast, chronic mitral regurgitation is characterized by high left atrial compliance and near-normal left atrial pressures with reduced forward output. Patients with chronic mitral regurgitation typically decompensate in the setting of volume overload.

Clinical Features

The characteristic presentation of acute mitral regurgitation is one of fulminant pulmonary edema. This is accompanied by a unique, harsh, midsystolic murmur that radiates to the base and not the axilla. Patients typically have no prior history of heart failure. The electrocardiogram may display signs of ischemia or infarction.

The presentation of chronic mitral regurgitation is similar to that of chronic systolic heart failure with clinical symptoms and signs of decompensated congestion. The murmur is classically described as holosystolic, heard best at the apex and radiating to the axilla. The ECG often reflects both left atrial and ventricular hypertrophy. Atrial fibrillation is common, and left atrial enlargement may be suggested by the chest x-ray. Echocardiography may demonstrate a normal or above-normal ejection fraction, but much of the diastolic flow is retrograde.

Management

When the diagnosis of acute mitral regurgitation is suspected, emergency echocardiography and cardiac catheterization will assess the degree of regurgitation and urgency for surgery. Initial stabilization should include treatment of pulmonary edema with nitrates and diuretics. In a hypotensive patient, a counterpulsion intra-aortic balloon pump may provide temporary stabilization as a bridge to surgery.

The natural history of chronic mitral regurgitation is generally a very slow progression with a 15-year survival approaching 70% with medical therapy, including diuretics and afterload reducing agents. Once the ejection fraction falls below 60%, valve repair or replacement is advisable before the development of irreversible left ventricular dysfunction.

Aortic Stenosis

The most common cause of aortic stenosis is calcific degeneration, which is prevalent in the elderly with coronary artery disease. This also occurs in younger individuals with a bicuspid aortic valve. Aortic stenosis can also occur along with mitral stenosis in rheumatic heart disease.

Pathophysiology

The normal aortic valve area is greater than 3 cm². Significant obstruction occurs when the valve area is reduced by more than 50%. Critical aortic stenosis is defined as a valve area of less than 0.8 cm² or when the pressure gradient across the valve exceeds 50 mm Hg. Compensatory left ventricular hypertrophy can maintain cardiac output until the stenosis becomes severe. Further progression of disease is associated with left ventricular dysfunction, left atrial enlargement, and atrial fibrillation. Individuals with severe or critical aortic stenosis are preload dependent and have very little cardiovascular reserve. Disruption of the delicate balance between myocardial oxygen supply and demand (e.g., ischemia, rapid atrial fibrillation, dehydration, and acute blood loss) can result in precipitous decompensation.

Clinical Features

Classic symptoms of aortic stenosis progress from angina (increased demand due to wall stress and decreased supply due to reduction in perfusion pressure) to exertional syncope (fixed cardiac output and vasodepressor response) and congestive heart failure (diastolic and systolic dysfunction). In an older patient presenting with chest pain, particularly if seemingly preload dependent, the possibility of aortic stenosis should be considered.

The classic auscultatory finding in aortic stenosis is a crescendo-decrescendo systolic murmur heard best at the base (right second intercostal space) that radiates into the carotids and is associated with the presence of an S₂ gallop and a soft aortic component of S₁. Importantly, as the severity of disease increases, the murmur peaks later and becomes less apparent. Carotid pulses may be delayed (tardus) and diminished in intensity (parvus). The ECG typically reveals left ventricular hypertrophy. Echocardiography is required for assessment of the severity of stenosis and the presence of left ventricular dysfunction.

Management

The natural history of aortic stenosis is one of slow progression without symptoms for years. Once symptoms develop, survival
is markedly reduced unless the valve is replaced, and medical management has a limited role. Management of decompensated aortic stenosis in the acute setting centers on judicious fluid resuscitation, blood transfusion, restoration of sinus rhythm, and avoidance of vasodilators and diuretics and inotropic agents if possible. When there is no response to medical therapy and the patient is a candidate for valve replacement, an intra-aortic balloon pump may provide a bridge to surgery.

Aortic Insufficiency

Aortic insufficiency, whether acute or chronic, may reflect valvular abnormalities caused by a congenital bicuspid valve, rheumatic heart disease, or infectious endocarditis. In addition, aortic root abnormalities such as ectasia, aneurysm, or dissection may be associated with a variety of connective tissue diseases, including Marfan’s syndrome.

Pathophysiology

With acute aortic insufficiency, left ventricular compliance is low and left ventricular pressure increases rapidly, leading to acute pulmonary congestion. The pressure gradient between the aorta and the left ventricle is minimal. In chronic aortic insufficiency, the left ventricle dilates, allowing the heart to maintain normal or near-normal cardiac output despite significant regurgitation. The enhanced stroke volume results in a wide pulse pressure and the associated clinical signs. Congestion is typically associated with volume overload.

Clinical Features

Patients with acute aortic insufficiency may present with a history suggestive of aortic dissection or aneurysm or severe respiratory distress and even frank cardiogenic shock. Acute aortic insufficiency can present with subtle physical findings. The pulse pressure may not be widened, and the short, soft, diastolic murmur may be difficult to detect. Echocardiography, which may be required emergently, is diagnostic.

With chronic aortic insufficiency, a widened pulse pressure may be accompanied by a number of physical findings, such as a rapidly rising and falling carotid pulse (water-hammer or Corrigan’s pulse), spontaneous nailbed pulsations (Quincke’s sign), or a to-and-fro murmur over the femoral artery (Duroziez’s sign). A high-pitched, blowing, diastolic murmur at the left sternal border is characteristic of chronic aortic insufficiency. An Austin-Flint murmur, a soft diastolic rumble caused by the regurgitant stream against the mitral valve, may also be present.

Management

Acute aortic insufficiency is a surgical emergency requiring immediate valve replacement. Medical stabilization entails the cautious use of vasodilators and diuretics. Intra-aortic balloon counterpulsation is contraindicated in the presence of an incompetent aortic valve. In contrast, chronic aortic insufficiency is managed like other types of decompensated heart failure. Valve repair or replacement should be contemplated before the development of left ventricular systolic dysfunction.

Mitral Valve Prolapse

Mitral valve prolapse (MVP) is defined pathophysiologically as an abnormal movement of one or both of the mitral valve leaflets across the plane of the valve during systole. Although generally a benign condition, it is infrequently associated with more serious cardiac pathology such as mitral regurgitation, endocarditis, and arrhythmias. Echocardiographic studies report a true prevalence of less than 1% in both men and women versus the previously reported 5% with a female predominance.

Pathophysiology

Structurally, MVP is characterized by myxomatous proliferation of the spongiosa layer within the mitral valve that results in abnormal billowing of the leaflet during systole. MVP may be associated with other connective tissue disorders, such as Marfan’s syndrome and Ehlers-Danlos syndrome. Although any of the leaflets may prolapse, involvement of the posterior leaflet is more likely to be associated with mitral regurgitation and other cardiovascular complications.

Clinical Features

MVP is associated with a wide variety of clinical symptoms, including chest pain, palpitations, dyspnea, lightheadedness, and fatigue. However, appropriately controlled clinical studies, such as the Framingham Heart Study, suggest that patients with MVP and control subjects may be equally symptomatic. The classic auscultatory features of MVP are a mid-systolic “click” followed by a mid-systolic to late systolic murmur over the mitral area. This click results from snapping of the chordae tendineae during the prolapse of the valve.

Diagnostic Strategies

The typical auscultatory findings should suggest MVP that is confirmed by echocardiography. Symptoms attributed to MVP, however, are often not explained by the degree of prolapse or mitral regurgitation. In some of these patients, autonomic or neuroendocrine dysfunction may be a cause of nonspecific symptoms.

Management

Propranolol or cardioselective beta-blockers may control symptoms such as palpitations, chest pain, and anxiety. Lifestyle modifications, such as exercise, relaxation techniques, and avoidance of ethanol or caffeine and other stimulants can also be helpful. Often, simple reassurance about the benign nature of the disease will suffice. The 2007 American Heart Association endocarditis prophylaxis guidelines no longer require consideration of mitral valve prolapse as one of the conditions requiring antibiotic prophylaxis.

Complications of Prosthetic Valves

Prosthetic heart valves are classified as either mechanical, constructed entirely of synthetic material, or biologic. The latter category includes whole valve transplants (porcine or human) as well as bioprosthetic valves manufactured from bovine pericardium. All prosthetic heart valves are associated with complications ranging from structural failure and thrombosis to systemic embolization, hemolysis, endocarditis. The diagnosis of a prosthetic valve complication can be challenging because symptoms and signs are often subtle. The overall incidence of complications is approximately 3% per year.

Primary structural failure is extremely uncommon with modern mechanical valves. When it does occur, the presentation is one of acute severe regurgitation and shock, mandating emergent replacement. With biologic valves, in contrast, struc-
tural failure is less dramatic but relatively more common. At 10 years, 20 to 30% of bioprosthetic valves will exhibit evidence of structural failure, and most are replaced electively. Symptoms are characteristically insidious in onset and mimic native valve disease.

Prosthetic valve thrombosis has an incidence of approximately 2% per year, both with biologic valves and with appropriately anticoagulated mechanical valves. Symptoms are of variable duration, generally subacute, and typically mimic congestive heart failure. The diagnosis is often initially overlooked, and untreated mortality approaches 15%. On physical examination, the diagnosis is suggested by a decreased or absent valve click, a new regurgitant murmur, or a louder than expected stenotic murmur. Echocardiography may demonstrate the thrombus or restricted leaflet motion suggesting obstruction. Treatment options include fibrinolytic therapy and surgery.37

The incidence of systemic embolization from a prosthetic valve is approximately 1% per year. Compared to patients with aortic valve prostheses, those with mitral valve prostheses have twice the risk of systemic embolization, with an incidence roughly the same in the case of a biologic valve or mechanical valve in an appropriately anticoagulated patient. The target international normalized ratio is 3.0 to 3.5 with a mechanical mitral valve versus 2.5 to 3.0 with an aortic valve. The vast majority of diagnosed embolic events (85%) involve the central nervous system, and roughly half of these result in permanent impairment. In this context, the risk of continued anticoagulation and possible hemorrhagic conversion must be weighed against the risk of a second embolic event.

Hemolytic anemia resulting from sheer forces around a prosthetic valve is usually mild and subclinical, but it may be severe in up to 15% of patients with certain prostheses. Presenting features can be subtle and include dyspnea, fatigue, jaundice, or dark urine. Iron replacement is effective in the majority of patients, although transfusion can be required, and reoperation may be indicated if hemolysis is due to a periprosthetic leak or other structural failure.

The incidence of prosthetic valve endocarditis is highest during the initial months following surgery and is similar for both mechanical and bioprosthetic valves.11 Early prosthetic valve endocarditis (within 60 days of surgery) is presumed to be caused by a pathogen acquired perioperatively and is associated with higher morbidity and mortality, whereas late prosthetic valve endocarditis is more likely related to transient bacteremia and is generally associated with a more benign course. As with other forms of endocarditis, fever is by far the most common presenting symptom, and other manifestations are quite variable. Echocardiography can identify vegetations, but a normal study does not rule out endocarditis. In the ED, the diagnosis of prosthetic valve endocarditis is presumptive since the definitive diagnosis requires blood cultures or biopsy. As such, prosthetic valve patients with no obvious extracardiac source of fever, particularly within 60 days of surgery, should be considered for inpatient admission.

### KEY CONCEPTS

- Many patients who present early in the bacteremic phase of IE lack a murmur and are indistinguishable from those with a viremia.
- Patients with a moderate to high suspicion of endocarditis require blood cultures, echocardiography, and admission for definitive diagnosis and initiation of empiric therapy.
- Prophylaxis for IE is rarely if ever indicated for procedures performed in the ED.
- Acute rheumatic fever is a delayed, nonsuppurative complication of streptococcal pharyngitis characterized by arthritis, carditis, chorea, subcutaneous nodules, and erythema marginatum.
- Patients with valvular stenosis (mitral and aortic) typically present with advanced disease, often exacerbated by atrial fibrillation.
- In patients with critical aortic stenosis, excessive preload reduction is to be avoided.
- In patients with acute aortic insufficiency, classic physical findings may be absent.
- Complications of prosthetic heart valves range from structural failure and thrombosis to systemic embolization, hemolysis, and endocarditis.

Hypertension

Richard O. Gray

PERSPECTIVE

For most of the 20th century, elevated blood pressure (BP) readings were thought to be associated with, but not causing, morbidity and mortality. Not until large population-based studies in the 1960s, such as the Framingham study, did physicians begin to focus on hypertension as a treatable risk factor for stroke, myocardial infarction (MI), peripheral vascular disease, congestive heart failure, and renal disease. Medical management of hypertension has reduced stroke mortality by 50% on an age-adjusted basis and has probably contributed to the decline in mortality from coronary artery disease. As a matter of public health, however, much remains to be done in the treatment of hypertension. Although approximately 75% of patients with chronically elevated BP are aware of their disease, as few as one half to one fourth of these patients are adequately treated and most surveillance data suggest this is not improving. Although hypertension may be epidemic, it rarely represents an emergency condition for the individual patient. In the absence of acute end-organ damage, it is rarely, if ever, necessary to lower a patient’s BP acutely in the emergency department.

Hypertension is frequently encountered in the emergency department (ED), where many factors can cause elevated BP. Patients may measure their own blood pressure in a retail pharmacy and present to the ED concerned that a symptom they are experiencing is caused by the blood pressure elevation. Anxiety and pain often cause transient hypertension, but evaluation of the patient for evidence of acute end-organ ischemia is important. Most patients, even those with an exacerbation of chronically elevated BP, show a substantial decrease in pressure without intervention during a short observation period in the ED. Even if the patient’s BP does remain elevated, urgent treatment is rarely beneficial or indicated, unless there is evidence of end-organ damage. Patient education and appropriate referral for long-term management should be provided.

P PRINCIPLES OF DISEASE

Definition and Determination of Hypertension

The Joint National Committee on Prevention, Evaluation, and Treatment of High Blood Pressure in its seventh report has dramatically changed how it classifies hypertension. In adults, a sustained systolic pressure less than 120 mm Hg and a diastolic pressure less than 80 mm Hg are considered normal. If the systolic pressure is between 120 and 139 mm Hg or if the diastolic pressure is between 80 and 89 mm Hg, the term pre-hypertension is applied, reflecting that the lifetime incidence of hypertension in these individuals is twice that of individuals in the “normal” range. The patient with a sustained systolic pressure of 140 mm Hg or higher or a diastolic pressure higher than 90 mm Hg is considered to be hypertensive. If hypertension, as defined by these arbitrary values, is not controlled, the patient is at great risk for long-term morbidity and mortality. The diastolic pressure is the primary determinant of future cardiovascular risk and is the most prevalent form of hypertension in patients younger than 50 years. In the two thirds of adults older than 65 years who have hypertension, systolic hypertension is more common and represents their greatest cardiovascular risk. Even isolated systolic hypertension in elderly patients is a significant risk factor for cardiovascular disease, especially when combined with other risk factors. In older patients, an elevated pulse pressure (determined by subtracting diastolic from systolic pressure) is an equally significant risk factor for stroke and MI.

Proper technique is required to obtain accurate BP readings. In patients with large extremities, a standard-size cuff may give a falsely elevated BP. A larger cuff should be used. With rapid deflation, inertia causes a gap between the actual pressure in the cuff and the measured pressure on the gauge. The systolic pressure should be recorded when the first tapping sound is heard as the cuff is deflated. Although several endpoints have been used to define diastolic pressure, the most widely accepted is the total disappearance of sound. In patients who do not have complete disappearance of these sounds, the point of distinct muffling should be recorded as the diastolic pressure.

A single elevated BP does not necessarily mean that the patient has hypertension. This is especially true in children. BP measurement should be repeated after the patient is in a reclining position for at least 10 minutes and should be checked in both arms. If the second reading is also elevated or close to the hypertensive range, the patient should be advised of the potential for hypertension and referred for repeated blood pressure determinations in an ambulatory care setting.

Pathophysiology

Hypertension is not a single disease but, rather, the result of a number of disease processes. By far the most common cate-
gory is essential hypertension. No specific cause of essential hypertension has been identified, although heredity, age, race, obesity, and the amount of dietary sodium may contribute to elevated BP.\textsuperscript{12} Prehypertension has been intensely studied because patients who later become hypertensive may provide clues about the physiologic changes that eventually produce a fixed elevation of BP. Two major theories exist: (1) hypertension results from alterations in the contractile properties of smooth muscle in arterial walls, and (2) alterations of arterial smooth muscle are a response to chronically elevated BP resulting from a primary failure of normal autoregulatory mechanisms. Research has focused on the role of calcium ions in vascular smooth muscle. Vascular tone depends on a transmembranous supply of calcium ions, and calcium antagonists suppress virtually all vasoconstrictive responses of vascular smooth muscles, including the peripheral resistance vessels.

Most patients with established hypertension have elevated peripheral arterial resistance and normal cardiac output. The findings are similar in the majority of prehypertensive individuals, many of whom have decreased plasma volume and elevated heart rate. This tachycardia seems to be caused not by an increased sympathetic tone but by a decreased parasympathetic tone. Autoregulatory mechanisms are blunted, and pharmacologic autonomic blockade has minimal effect on BP.

Other patients with hypertension have a very different circulatory status with an elevated cardiac output and hyperkinetic circulation. The increase in cardiac output results from an increase in both heart rate and stroke volume. There appears to be a large sympathetic component with an increase in both cardiac beta-adrenergic and alpha-adrenergic tone. Autonomic blockade returns the BP readings to normal.

**Renin, Angiotensin, and Aldosterone**

The role of renin and angiotensin as a cause of essential hypertension is not clear. Renin is an enzyme produced by the kidney that splits off angiotensin I from a plasma globulin precursor.\textsuperscript{13} Angiotensin I is converted by an enzyme in the lung to produce angiotensin II. Angiotensin II is a potent vasoconstrictor and also stimulates aldosterone production in the adrenal gland. Figure 82-1 depicts the renin-angiotensin-aldosterone axis. Patients with hypertension may be divided into clinical groups according to renin levels. Determining the renin-sodium profile, which is the plasma renin activity measured against the 24-hour urine sodium content, is especially useful in making this distinction.

In normal individuals, angiotensin effects depend on sodium levels. Inhibition of angiotensin-converting enzyme (ACE) has some effect on BP in normotensive individuals with normal total body sodium but greatly reduces BP in those with sodium depletion. When ACE inhibitors are administered to patients with hypertension, their acute effect on BP is closely related to the plasma renin activity. With chronic administration, however, the effect of ACE inhibitors on BP no longer correlates with pretreatment plasma renin activity.\textsuperscript{14} Elevated renin and angiotensin levels are responsible for the hypertension seen in ischemic renal disease, and angiotensin is a major contributor to maintaining the progressive rise of BP in accelerated hypertension. In the latter condition, renin and angiotensin levels are increased because of areas of renal ischemia secondary to arteriolar necrosis. ACE inhibitors or angiotensin blockers are clearly the drugs of choice in hypertensive patients with diabetes or decreased left ventricular function or both.

The role of hyperaldosteronism in essential hypertension is debatable.\textsuperscript{15,16} Primary hyperaldosteronism may affect 8 to 32% of patients, depending on the population of patients screened, and it should be investigated in patients with refractory hypertension.\textsuperscript{17} Hyperaldosteronism may occur with an isolated adrenal aldosteronoma, bilateral microscopic multinodular adrenal hyperplasia, macroscopic adrenal hyperplasia, a genetic form called glucocorticoid remediable hyperaldosteronism, or even adrenal carcinoma. Spontaneous hypokalemia in a patient with hypertension should suggest primary hyperaldosteronism, but this is not invariably present. Catecholamine levels may also be abnormal. Primary hyperaldosteronism is usually investigated by a comparison of the ratio of plasma aldosterone concentration to plasma renin activity and confirmed by a failure to inhibit aldosterone levels in the urine or plasma with sodium loading.\textsuperscript{18}

**Renal Disease**

Although essential hypertension is the most common form of hypertension, early identification of secondary hypertension is important because it may lead to cure or at least to a specific and much easier treatment regimen. Of these other causes, renal disease is the most prevalent. All types of renal disease are associated with hypertension, although a direct relationship can be demonstrated only in cases of unilateral renal disease, in which the removal of the affected kidney cures the hypertension. This is clear in unilateral renal arteriostenosis. Renovascular hypertension results from the overproduction of renin secondary to reduced blood flow through the stenotic renal artery. The increased levels of renin lead to activation of the angiotensin pathway and resultant hypertension. If the renin level in the affected kidney is more than 50% higher than the level in the normal kidney, a complete or partial cure of the hypertension can be anticipated with surgery.

Another vascular lesion associated with arterial stenosis and hypertension is fibromuscular dysplasia of the renal arteries.\textsuperscript{19,20} This disease is predominant in young white women, and flank bruits are often present. The various types affect different areas of the renal arteries. The result is progressive hypertension. Neither pharmacologic therapy nor surgical revision offers a cure, but both treatments slow the disease process and help preserve functional renal mass.
Primary renal disease can produce hypertension, but the exact mechanism is unknown. Up to 70% of patients with chronic pyelonephritis have elevated BP. Local ischemia within the kidney is suspected as the cause of hypertension. Some authors suggest local microvascular renal disease as the final common pathway underlying essential hypertension. Hypertension in patients with nonspecific glomerulonephritis may result from arteriolar lesions producing ischemia at the level of the individual nephron. With the exception of renin-secreting renal tumors, the exact cause of hypertension associated with the various nephropathies is unknown.

Arterial Disease

Abnormalities of the large arteries can also produce hypertension. Although uncommon, coarctation of the aorta is an important cause of secondary hypertension, and early surgical intervention can greatly improve the patient’s prognosis. The triad of upper extremity hypertension, a systolic murmur best heard over the back, and delayed femoral pulses should alert the examiner to the diagnosis of coarctation. Hypertension appears to result from the combined effects of mechanical obstruction and activation of the renin-angiotensin system.

Early diagnosis of coarctation is important because surgical repair results in a consistent and sustained lowering of BP. In adults, renal artery stenosis is an important cause of accelerated onset of significant hypertension, and renal artery ultrasonography or angiography is advisable (on an ambulatory basis) for patients with this type of onset of disease.

Loss of elasticity in the larger arteries associated with the aging process produces systolic hypertension as well as elevations in pulse pressure. Arteriosclerosis from the deposition of collagen and smooth muscle hypertrophy plays a major role in the age-dependent stiffness of the central vasculature. Previously, elevated systolic pressure was not considered significant and frequently was not treated. The current literature strongly suggests that isolated systolic hypertension is associated with an increased risk of stroke, heart disease, and renal failure and should be treated. The cause of reduced elasticity in the arteries associated with isolated systolic hypertension has not been fully determined. Endothelial dysfunction that develops over time with both aging and hypertension may play a critical role in this process. Other factors that decrease central vascular compliance include high dietary salt intake, tobacco use, elevated homocysteine levels, and diabetes.

Glucocorticoids

Excessive glucocorticoids are associated with hypertension, and the most common cause is iatrogenic steroid therapy. Endogenous overproduction is rare and results from excessive adrenocorticotropic hormone (ACTH) production by a pituitary tumor, ectopic ACTH production by a nonpituitary tumor, or glucocorticoid production by tumors of the adrenal cortex. These patients show other signs and symptoms of excessive glucocorticoids, including centripetal fat distribution, striae, easy bruising, muscular weakness, and poor healing. The hypertension associated with hyperadrenalinism is usually not severe and can be controlled by treating the underlying disease process.

Thyroid and Parathyroid Disease

Both hyper- and hypothyroidism are associated with elevations in BP. In thyroid storm, patients are usually hypertensive and tachycardic, and beta-blockade is a mainstay of the acute management. Patients with hypothyroidism also present with hypertension as well as the other characteristic findings. Treatment of the hypothyroidism usually results in correction of the hypertensive state. Hypertension with hypercalcemia suggests hyperparathyroidism, which is another rare secondary cause of hypertension.

Sleep Apnea

Both obstructive and central forms of sleep apnea are associated with hypertension. Apnea itself is associated with a significant increase in BP. Approximately 50% of patients with sleep apnea have daytime hypertension, but many have other risk factors for hypertension, such as obesity or alcohol consumption. Studies suggest that treatment of nocturnal hypoventilation may improve daytime BPs.

Pheochromocytoma

Pheochromocytomas are responsible for less than 1% of cases of hypertension. More than 90% of these patients are curable with early diagnosis. Pheochromocytomas produce catecholamines and arise from cells of the sympathetic nervous system. The most common site is the adrenal medulla. Patients with neurofibromatosis (von Recklinghausen’s disease) have an increased incidence of pheochromocytoma. Pheochromocytoma, medullary carcinoma of the thyroid, and parathyroid adenomas form the triad of multiple endocrine neoplasia (adenomatosis), type 2.

The characteristic feature of pheochromocytoma is paroxysms of hypertension associated with palpitations, tachycardia, malaise, apprehension, and sweating. Many patients have a persistently elevated BP interspersed with episodes of greater hypertension that occur sporadically and vary greatly in severity, frequency, and duration. These episodes may be related to physical and emotional stress, eating, position, or even micturition. A prodrome of apprehension and nonspecific abdominal pain progressing to headache, palpitations, and angina may be seen. Because of the episodic nature of this syndrome, the patient is often dismissed with a diagnosis of hyperventilation syndrome or anxiety. An excessively elevated BP associated with these symptoms is enough to suggest a pheochromocytoma. Patients may also display increased BP when treated with beta-blocking agents (beta-blockers).

The diagnosis is confirmed with elevated urinary levels of catecholamines, metanephrines, and vanillylmandelic acid, usually to more than twice the normal levels. Treatment consists of alpha-blockade to control hypertension and subsequent beta-blockade for the control of cardiac dysrhythmias. After the hypertension is adequately controlled, the tumor should be surgically removed.

Other Causes

Eating foods that contain large amounts of tyramine can cause episodic hypertension (Box 82-1). Tyramine causes release of norepinephrine stored in nerve endings. This response is normally transient; tyramine is rapidly destroyed by monoamine oxidase. Problems arise if a patient is being treated with a monoamine oxidase inhibitor (MAOI), which protects tyramine from destruction. Relatively small amounts of tyramine can cause severe and prolonged hypertension. A number of therapeutic agents can also induce a hypertensive crisis in patients taking MAOIs. These include meperidine, the amphetamines, ephedrine, reserpine, guanethidine, and tricyclic antidepressants. The hypertension can be controlled by using an alpha-blocking agent (alpha-blocker) such as phentolamine.
Excess catecholamine effect can result from the acute withdrawal of clonidine or beta-blocker therapy. Clonidine acts centrally as an alpha-adrenoreceptor agonist. The sudden withdrawal of this agent may result in catecholamine excess and severe hypertension 16 to 48 hours later. Many of the symptoms associated with clonidine withdrawal are similar to those of pheochromocytoma, including anxiety, tremor, palpitations, and severe headache. Urinary catecholamine levels are markedly elevated. Treatment consists of restarting clonidine therapy or using alpha-blockers. This characteristic limits clonidine’s usefulness as an antihypertensive agent in noncompliant patients.

Alcoholism or alcohol withdrawal may precipitate hypertension. Use of nonsteroidal anti-inflammatory agents, including the selective cyclooxygenase-2 inhibitors, may inhibit the renin-angiotensin system.27,28

Emergency Department Presentation

Hypertension is seen in the ED in the following four general ways:

1. “Hypertensive emergency” or “hypertensive crisis” with acute end-organ ischemia
2. “Hypertensive urgency,” a historical term of no clinical value related to arbitrarily elevated BP with nonspecific symptoms. These patients probably are best referred to simply as having poorly controlled or inadequately controlled hypertension.
3. Mild hypertension without end-organ ischemia
4. Transient hypertension related to anxiety or the primary complaint

Clinical Presentation of Hypertensive Emergencies

A small number of hypertensive patients present with a true hypertensive emergency. BP is usually markedly elevated and there is evidence of acute dysfunction in the cardiovascular, neurologic, or renal organ system (Box 82-2). These conditions are true medical emergencies and mandate early reduction of BP, preferably within 1 hour of identification of the condition.2,29,30

In the past, the range of hypertensive emergencies included patients who presented with any emergent condition associated with a marked elevation of BP. The elevated BP in these patients is often a physiologic response to an acute condition, and aggressive treatment for hypertension may actually increase morbidity and mortality. This is especially true for patients with acute intracranial events.31

Hypertensive Encephalopathy

Throughout the normal range of BP, cerebral blood flow is maintained by fluctuations in the vascular tone of the cerebral resistance vessels known as autoregulation. Hypertensive encephalopathy is an uncommon syndrome resulting from an abrupt, sustained rise in BP that exceeds the limits of cerebral autoregulation of the small resistance arteries in the brain. Above a mean arterial pressure (MAP) of approximately 160 mm Hg, autoregulation may be unable to control cerebral blood flow, resulting in vasospasm, ischemia, increased vascular permeability, punctate hemorrhages, and brain edema. Immediate reduction of BP by 30 to 40% reverses the vasospasm. Excessive reduction of BP must be avoided to prevent increasing cerebral ischemia. In normal humans, autoregulation operates above an MAP of approximately 60 mm Hg. In patients with uncontrolled hypertension, however, the level of autoregulation is elevated, cerebral ischemia may occur at a much higher MAP, and BP reduction should generally not take the MAP below 100 mm Hg.

Hypertensive encephalopathy is (1) acute in onset and (2) reversible. Patients present with severe headaches, vomiting, drowsiness, and confusion. Seizures, blindness, focal neurologic deficits, or coma may occur. Papilledema is usually present, along with significant hypertensive retinopathy. Differential diagnosis includes strokes and intracranial hemorrhage (ICH), meningoencephalitis, brain tumors, and metabolic coma. Careful neurologic examination often differentiates between a space-occupying lesion and hypertensive encephalopathy because focal deficits from hypertensive encephalopathy usually do not follow a singular anatomic pattern. They may occur on opposite sides of the body or may have multiple areas of involvement. Computed tomography is usually normal, and the electroencephalogram shows only nonspecific abnor-
Hypertensive encephalopathy is a true medical emergency; untreated patients develop increasing coma, and death may ensue within a few hours. Rapid, controlled reduction of BP is essential with a careful reduction of the MAP by 25% or to a diastolic pressure of 100 to 110 mm Hg over 1 hour. The standard treatment regimen in the United States has long been intravenous (IV) nitroprusside, but labetalol is now widely used, and other agents, such as fenoldopam, nicardipine, and enalaprilat, have also proven effective. Clevidine is a newer ultra-short-acting calcium channel blocker under investigation for the management of hypertensive emergencies.32 Use of an oral or nontitratable agent may result in excessive reduction of BP and irreversible cerebral ischemia. Nifedipine was widely used in the past for rapid mitigation of hypertension, particularly in the context of heart failure, but it has largely fallen out of favor because of numerous serious adverse effects related to uncontrolled hypotension and sympathetic release.30,33

All patients with hypertensive encephalopathy should be hospitalized, and establishment of an arterial line for BP monitoring is desirable.

### Malignant Hypertension

Malignant (accelerated) hypertension is severe hypertension associated with evidence of acute and progressive damage to end organs. This syndrome can occur at any time in the clinical course of hypertension. The diastolic BP is usually greater than 130 mm Hg. Readings below this level are seldom associated with either malignant hypertension or hypertensive encephalopathy, although rarely either can occur with diastolic pressures as low as 110 mm Hg. The vast majority of patients with diastolic pressures higher than 130 mm Hg do not develop either of these clinical syndromes. Malignant hypertension affects only 1% of the hypertensive population.50

The pathologic process begins when a rapid, sustained rise in BP overpowers the high-pressure autoregulatory mechanism, causing the small arterioles to dilate. As these vessels dilate, pressure in the proximal capillary beds increases, and fluid leaks into the tissues. The arterioles may rupture and leak plasma and blood, resulting in fibrin deposition into their walls. This combination of necrosis of myofibrils in smooth muscle cells, leaking of plasma, and fibrin deposition in the walls of arterioles is fibrinoid necrosis and is responsible for end-organ damage. These changes within the small arterioles are directly visible in the retina as linear hemorrhages dissecting along nerve fibers. The disruption of the arteriolar wall causes obstruction of the vessel and ischemia downstream. In the retina, this produces a cotton-wool spot that consists of swollen, ischemic axons. The aggregation of materials within the ischemic axons produces a nuclear-like structure termed the cytoid body. Hard exudates, which consist of lipid deposits located deep in the retina, are also a common finding. These fine, punctate, shiny lesions can be distinguished from cotton-wool spots, which are larger and have blurred edges and a more diffuse appearance.

Patients with malignant hypertension appear ill and often present with complaints of severe headache, blurred vision, dyspnea, and chest pain or with symptoms of uremia. If untreated, it may result in acute renal failure, severe cardiac decompensation, MI, hypertensive cerebral hemorrhage, or hypertensive encephalopathy.

The diagnosis of malignant hypertension cannot be made on the basis of BP readings alone. In addition to elevated BP, these patients must have evidence of acute end-organ damage as a result of the hypertension. The physical examination may reveal an enlarged left ventricle and rales at the lung bases. Marked retinal findings are often present, including linear hemorrhages and cotton-wool patches. Acute elevation of blood urea nitrogen and serum creatinine or the presence of hematuria indicates involvement of the kidneys. Rarely, the blood smear reveals red cell fragments, and fibrin degradation products are elevated, giving a clinical picture compatible with microangiopathic hemolytic anemia. Left ventricular hypertrophy and strain are usually seen on the electrocardiogram (ECG). The chest radiograph may reveal cardiomegaly and evidence of congestive heart failure.

Malignant hypertension is treated in a manner similar to that for hypertensive encephalopathy by the judicious lowering of MAP by 25% of pretreatment levels over the initial minutes to hours and then toward a target of 160/100 over 2 to 6 hours, avoiding excessive decreases in pressure that may precipitate renal, cerebral, or coronary ischemia.2,29,30

All patients with malignant hypertension should be hospitalized, and invasive BP monitoring may be preferable. An easily titratable agent, such as labetalol, nitroprusside, or fenoldopam, is used, with the goal of avoiding any episodes of hypotension.

### Stroke Syndromes

Hypertension is often associated with stroke syndromes.34 In most of these patients, elevated BP is the physiologic response to the stroke and is not the immediate cause. Approximately 85% of strokes are nonhemorrhagic, and most patients who have embolic or thrombotic strokes without an associated hemorrhage do not sustain substantially elevated BP. These patients have mild to moderate hypertension that has little effect on the clinical course and may portend a better prognosis.51 In patients with long-standing hypertension, rapid reduction of BP may further reduce cerebral blood flow and cause increased ischemia.

Except in cases of stroke caused by aortic dissection, antihypertensive therapy is not indicated and may be harmful. Some have recommended careful antihypertensive treatment for patients with persistent, extreme elevations of BP after a stroke (e.g., diastolic pressure >140 or MAP >130 mm Hg), but data do not support this approach.56 The best current advice is to limit reductions in BP for acute stroke patients to circumstances in which the BP elevation is causing injury to another end organ, for example, myocardial ischemia. In these cases, BP should be lowered cautiously to mitigate the effects on the other end organ, but the ischemic neurologic deficit must not increase. When fibrinolytic therapy is administered, significant elevations of BP greatly increase the risk of secondary ICH, and patients with persistent pressures higher than 185/110 mm Hg should not receive thrombolytic therapy until their blood pressure is controlled.56,57

Patients with ICH often have a profound, reactive elevation of BP. In most patients with ICH, hypertension is secondary to the increased intracranial pressure (ICP) and to irritation of the autonomic nervous system. This type of hypertension often disappears rapidly and has little effect on clinical outcome. Deterioration in most patients with ICH results from hemorrhagic enlargement or edema. Data to support the pharmacologic lowering of BP in patients with ICH are lacking.54 Persistent hypertension is associated with a poorer functional outcome after ICH, and traditionally many centers treat hypertension after ICH. Because cerebral perfusion pressure (CPP) depends on systemic pressure, this practice may not be beneficial. Although no conclusive evidence indicates that treating hypertension in the acute period after ICH is beneficial, modest reductions in BP (e.g., 20% reduction in MAP) have
not been clearly associated with a worse outcome and may be advisable after discussion with the vascular neurosurgery consultant.

If BP reduction is pursued in these patients, labetalol is the agent of choice. Labetalol and other adrenergic blockers shift cerebral autoregulation to lower pressures in patients with intracranial mass lesions. This shift preserves cerebral blood flow at lower pressures. Adrenergic blockers also preserve reactivity to carbon dioxide partial pressure (PCO₂). Nicardipine also has been used successfully to treat hypertension in the setting of acute intracerebral hemorrhage. ACE inhibitors also shift autoregulation but have not been extensively studied in patients with ICH or elevated ICP. Vasodilators such as nitroprusside increase ICP, impair cerebrovascular reactivity to changes in Pco₂, and exacerbate any decrease in CPP for a given level of BP reduction.

Pulmonary Edema

Most patients with congestive heart failure have some degree of increased peripheral vascular resistance (PVR) and resultant hypertension; this is a normal response. The degree of BP elevation is moderate and does not represent a medical emergency. When poorly controlled, however, long-standing hypertension produces myocardial hypertrophy, which continues until the hypertrophy can no longer overcome the increased PVR; then the left ventricle begins to fail and dilates.

In most patients with this combination, the hypertension results from increased PVR caused by elevated catecholamines associated with the stress of pulmonary edema. With standard treatment of pulmonary edema, including morphine, nitrates, oxygen, ACE inhibitors, and furosemide, catecholamine levels decrease and BP returns rapidly toward normal. In a small number of patients, pulmonary edema results from an abrupt, severe elevation of BP that precipitates acute left ventricular failure. The BP must be lowered to reverse this process. Nitroglycerin is usually the first drug used, but if it does not adequately reduce BP, nitroprusside should be the next choice. Nitroprusside does not cause sodium retention; it improves cardiac function, especially in the failing heart, and can be carefully titrated and rapidly reversed. ACE inhibition has also been used successfully as an adjunct in the acute treatment of pulmonary edema. Although pressure often decreases significantly with treatment of congestive heart failure, stroke syndromes can occur as a consequence of hypotension occurring during the treatment of acute pulmonary edema.

Cardiac Ischemia

Hypertension and angina are often found together. If severe hypertension is present with concurrent angina, immediate lowering of BP is indicated to prevent myocardial damage. In most of these patients, nitroglycerin and an IV beta-blocker, such as metoprolol, are the agents of choice. ACE inhibitors may be a useful adjunct and have also been shown to reduce mortality in patients with MI. Calcium channel blockers may be a useful alternative for patients unable to tolerate beta-adrenergic blockade because of bronchospasm. Nitroprusside may induce a reflex tachycardia and must be used with caution in patients with cardiac ischemia. With systemic fibrinolytic therapy, aggressive BP control is required due to the risk of ICH.

Renal Failure

The most important cardiovascular complication of chronic renal failure (CRF) is hypertension. Uncontrolled hypertension accelerates the development of cardiovascular problems, which are the most common cause of death in both dialysis and transplant patients. Hypertension also causes further damage to diseased kidneys. Hypertension may appear at any time during the course of CRF and occurs in more than 80% of patients with advanced renal failure. Glomerular disease is associated with a higher incidence of hypertension than is tubulointerstitial disease. In the absence of hypertension, CRF worsens more slowly; if hypertension is present but controlled, the progression of CRF can be delayed. Patients with renal failure secondary to malignant hypertension often demonstrate a transient worsening of renal function during their initial treatment period. After this initial period, renal function improves.

The primary cause of hypertension for patients with CRF is an actual or relative increase in extracellular volume secondary to sodium retention, as well as activation of the renin-angiotensin system in diseased kidneys. Glomerular disease is associated with greater sodium retention than is tubulointerstitial disease. Diuretics to improve fluid balance and ACE inhibitors, angiotensin receptor blockers, or calcium channel blockers should be the first-line agents to control hypertension in patients with renal failure.

Severe elevation of BP may lead to acute renal failure or may exacerbate CRF. Immediate reduction of BP is required. Fenoldopam is the drug of choice, although the IV calcium channel blocker nicardipine and nitroprusside are reasonable alternatives.

Pregnancy

Hypertension is one of the most common complications of pregnancy, occurring in 5 to 10% of all pregnancies (see Chapters 176 and 177). Antihypertensive agents may be needed but in most patients can be delayed until hospital admission. The exceptions are those women with severe preeclampsia or eclampsia, both of which represent hypertensive emergencies and can occur without an extreme elevation of BP. Any acute elevation of the diastolic BP higher than 100 mm Hg in the pregnant patient represents a true hypertensive emergency. The treatment of hypertensive emergencies of pregnancy should include reduction of BP prevention and control of seizures, and early obstetric consultation. Although it may cause tachycardia and hypotension, the classic antihypertensive agent of choice in preeclampsia has been IV hydralazine, but this is falling out of favor due to its relative unpredictable dose-response curve. Alternative antihypertensives include labetalol and nicardipine. Nitroprusside is relatively contraindicated because of the potential for accumulation of cyanide in utero. Because of this potential complication, nitroprusside should be reserved for those patients in whom other agents have failed. Oral nifedipine has also been used in this setting, although, as in other conditions, overshoot hypotension has been observed. Preeclampsia and eclampsia are true hypertensive emergencies and are discussed in Chapter 176.

Aortic Dissection

Aortic dissection is associated with a history of hypertension (see Chapter 83). Medical therapy consists of reducing BP to limit the extent of the dissection. The goals of medical therapy are to lower BP to a systolic level of 100 to 120 mm Hg and to reduce the ejection force of the heart. Classically, a beta-blocker such as esmolol is given to control reflex tachycardia,
whereas a vasodilator (nitroprusside, fenoldopam, or nicardipine) is used to reduce BP. Single drug management using the combined alpha/beta-blocker labetalol is commonly used and successful. 29,30

### MANAGEMENT OF HYPERTENSIVE EMERGENCIES

#### Vasodilators

**Fenoldopam**

Fenoldopam (Corlopam) is a peripheral dopamine-1 receptor agonist approved for the treatment of hypertensive emergencies. Dopamine-1 receptors are located postsynaptically in the systemic and renal vasculature and mediate systemic, renal, and mesenteric vasodilation as well as natriuresis. In contrast to treatment with nitroprusside, fenoldopam therapy improves renal function acutely in patients with malignant hypertension. 47 Fenoldopam does not cross the blood-brain barrier, has a rapid onset of action, and has an elimination half-life of 9 minutes. 48-50 Reflex tachycardia, flushing, and headache may be observed, but hypotension occurs less often than with nitroprusside therapy.

The initial dose of fenoldopam is 0.1 µg/kg/min, and the dose is titrated in 0.1 µg/kg/min increments every 15 minutes until the desired effect is seen. The maximum recommended dose is 1.6 µg/kg/min. Fenoldopam represents a reasonable alternative to nitroprusside in the treatment of hypertensive emergencies without the concerns of light sensitivity and cyanide or thiocyanate toxicity and also with fewer hypotensive episodes. Fenoldopam has been used in trials without invasive BP monitoring. 48

**Nicardipine**

Nicardipine (Cardene) is a parenteral dihydropyridine calcium channel blocker that has become very popular in the treatment of postoperative hypertension. Nicardipine is titratable, has less negative inotropic effect, and induces less tachycardia than does nifedipine. Nicardipine acts predominantly as a vasodilator, but as with other calcium channel blockers, caution must be used when it is administered to patients with left ventricular failure. Nicardipine is administered as an infusion beginning at 5 mg/hr, increasing the infusion rate every 15 minutes until the desired reduction of BP has been achieved, to a maximum dose of 15 mg/hr. Onset of action is 5 to 15 minutes and duration of action 4 to 6 hours. As with labetalol, an oral form may facilitate the transition from acute to chronic therapy.

Nicardipine is heavily metabolized in the liver, and caution must be used in patients with cirrhosis. Nicardipine decreases the glomerular filtration rate in patients with compromised renal function, a trait shared by nitroprusside. As with the other vasodilators, headache, flushing, and tachycardia are the most common adverse reactions seen with nicardipine. Nicardipine has been best studied in pregnant patients and in the settings of postoperative and malignant hypertension, in which it appears to be a less toxic alternative to nitroprusside. 2,30,31

**Sodium Nitroprusside**

Nitroprusside (Nipride and Nitropress) is a powerful vasodilator with a direct effect on the smooth muscle of both resistance and capacitance vessels. Nitroprusside has historically been the agent of choice for most hypertensive emergencies (Table 82-1). Its rate of onset is extremely rapid, and its duration of action is very short. Nitroprusside does not usually worsen angina, but a coronary steal phenomenon may occur. 39 The cardiac response depends on the state of myocardial function. Because of the reduction of preload by venous dilation, the cardiac output often improves if congestive heart failure or borderline myocardial function is present. Because nitroprusside is a cerebral vasodilator, it may increase ICP secondary to increased cerebral blood flow. Nitroprusside is metabolized to thiocyanate and is excreted slowly by the kidneys. Cyanide is an intermediate metabolite, and its metabolism requires functioning liver, kidneys, and adequate bioavailability of thiosulfate. In the presence of renal failure or during prolonged nitroprusside therapy, the thiocyanate concentration may reach toxic levels of 10 mg/dL, and a clinical picture of weakness, hypoxia, nausea, tinnitus, muscle spasm, disorientation, and psychosis may develop. The prolonged use of nitroprusside may produce hypothyroidism by inhibition of iodine transport, and methemoglobinemia has occurred.

Nitroprusside must be used as an IV solution. As capacitance vessels dilate, the patient must be kept recumbent to prevent profound orthostatic hypotension. Because of nitroprusside’s short half-life, stopping the infusion returns the BP to pretreatment levels within 1 to 10 minutes. The amount of BP reduction is dose related. Elderly patients and those receiving antihypertensive medications are more sensitive to nitroprusside’s effects. In all patients, the starting dose should be 0.25 to 1.0 µg/kg body weight per minute. The average dose required for the control of hypertension is 3.0 µg/kg/min. Dosages greater than 800 µg/min are seldom required and should not be used for long periods because of the accumulation of cyanide and thiocyanate. Patients treated with nitroprusside should be admitted to the intensive care unit for close monitoring of BP, preferably by an intraarterial line. The drug should be diluted and given by an automatic infusion device. Nitroprusside is unstable in ultraviolet light, and the IV bag should be wrapped in opaque material. Only fresh solutions of nitroprusside less than 4 hours old should be used.

All types of hypertension respond to nitroprusside, although certain patients may not have an adequate response. Side effects are directly related to excessive vasodilation and resultant hypotension and can be avoided by careful monitoring of

ACE, angiotensin-converting enzyme.
BP and regulation of infusion rate. Extreme caution must be taken to avoid the extravasation of nitroprusside because local necrosis can be severe. Nitroprusside has not been proved to be safe during pregnancy and should be avoided because of the potential effect of thiocyanate on fetal thyroid tissue, the risk of cyanide poisoning to the fetus, and the possibility of fetal methemoglobinemia.

Nitroglycerin

Nitroglycerin is a vasodilating agent that acts predominantly on the venous system, decreasing left ventricular end-diastolic pressure. At normal doses, nitroglycerin has little effect on arterial vascular tone and reduces BP by reducing preload and cardiac output. These effects may be undesirable in patients with impaired cerebral and renal perfusion. Nitroglycerin use should be limited to patients with cardiac ischemia or pulmonary edema. Nitroglycerin may be administered either sublingually or intravenously. Care must be taken in patients with right ventricular dysfunction to avoid hypotension, which may exacerbate cardiac ischemia.

Hydralazine

Hydralazine (Apresoline) is a direct arteriolar vasodilator that was widely used in the past for the hypertensive emergencies of pregnancy. Recent studies, however, have shown that nicardipine and labetalol are superior agents in this setting, and hydralazine should not be considered first-line therapy for acute treatment of hypertensive emergencies in the ED. The usual starting dose of hydralazine is 5 mg IV, with repeated doses of 5 to 10 mg every 20 minutes as needed to keep the diastolic pressure below 110 mm Hg. Typically, a latent period of 5 to 15 minutes is followed by a progressive and at times precipitous fall in BP lasting for up to 12 hours. Hydralazine is also associated with significant reflex tachycardia, which may provoke angina in patients with coronary artery disease. Other common side effects are flushing, nausea, and headache. Chronic use is associated with a lupus-like syndrome that usually resolves with discontinuation of the medication.

Beta-Blockers

Labetalol

Labetalol (Trandate and Normodyne) is a selective alpha,-blocker and nonsselective beta-blocker with a ratio of alpha/beta-blockade between 1:3 and 1:7. It can be given orally or IV. Labetalol lowers BP by blockade of the alpha,-receptors in vascular smooth muscle and the cardiac beta-receptors. Because of the simultaneous beta-receptor blockade, the usual reflex tachycardia associated with vasodilators does not occur. Labetalol does not cause the significant drop in cardiac output associated with other beta-blockers. Although oral labetalol is less likely to produce orthostatic hypotension, IV use is marked by profound orthostatic changes. After IV labetalol, the patient should be kept in the supine position for several hours. Labetalol does not affect cerebral blood flow or renal function. With IV labetalol, BP generally decreases within 5 to 10 minutes, with maximum effect in 30 minutes.

The initial dose of labetalol is 20 mg infused over 2 minutes. The BP should be rechecked every 5 minutes, and if only minimal change occurs, an additional dose is given every 10 minutes in increments of 20, 40, or 80 mg to a total of 300 mg of labetalol, depending on BP response. A preferable approach may be to give the initial loading dose and then an infusion at 1 or 2 mg/min, which can be titrated upward. When given in this manner, labetalol appears to be a safe agent, with minimal adverse reactions. Because labetalol is a beta-blocker, it is contraindicated in patients with congestive heart failure, heart block, and asthma. Labetalol also appears to be contraindicated for treatment of hypertension secondary to pheochromocytoma because it may result in paradoxical hypertension.

Labetalol therapy cannot be as closely controlled or as quickly reversed as nitroprusside or fenoldopam therapy. However, use of labetalol may not require admission to an intensive care unit. Labetalol does not appear to exacerbate coronary artery disease or cause uncontrolled drops in BP.

The transition to oral therapy is smooth. After initial control of BP with IV labetalol, oral labetalol should be started when diastolic pressure rises 10 mm Hg. Labetalol is an excellent alternative to nitroprusside when constant BP monitoring is not feasible. Labetalol is superior as a single agent in patients who have aortic dissection or cardiac ischemia with intact left ventricular function.

Esmolol

Esmolol (Brevibloc) is an ultra-short-acting, selective beta,-blocker without intrinsic sympathomimetic activity. It typically has little effect on BP in normal individuals but may be very useful to control the reflex tachycardia seen with vasodilating agents such as nitroprusside. Esmolol is initiated with a loading dose of 500 µg/kg over 1 minute, followed by an infusion of 50 to 100 µg/kg/min. Maximal effect occurs in 5 minutes. If necessary, another bolus of 500 µg/kg is given, and the drip is increased by 50 µg/kg/min. This cycle may be repeated every 5 minutes until the desired heart rate response is seen, up to a maximum dose of 300 µg/kg/min. Because the elimination half-life of esmolol is 9 minutes, any effect resolves within 30 minutes of discontinuing the infusion, with substantial recovery from beta-blockade in 10 to 20 minutes. Contraindications are similar to those with labetalol, including cocaine overdose, pheochromocytoma, congestive heart failure, heart block, and reactive airway disease. Esmolol also causes tissue necrosis when extravasated into the soft tissue and may cause thrombophlebitis when infused into small veins.

Alpha-Blockers

Phentolamine (Regitine) is an alpha-blocking agent used for catecholamine-induced hypertensive crises (e.g., pheochromocytoma, MAOI crisis, and cocaine overdose). Phentolamine is usually given IV in 1- to 5-mg boluses, although it may be given as an infusion at a rate of 5 to 10 µg/kg/min. The effect is immediate and may last up to 15 minutes. Reflex tachycardia may be seen. After BP is under control, oral phenoxybenzamine, a long-acting alpha-blocker, may be used.

Enalaprilat and Enalapril

Enalaprilat (Vasotec) is a parenteral active metabolite of the ACE inhibitor enalapril. This drug has been studied in limited numbers of patients with true hypertensive emergencies. Hypotension is rare with the use of enalaprilat, but caution should be used in patients who may be volume depleted. The acute dose is 0.625 to 5 mg administered as a single bolus. Peak effects generally occur in 15 minutes but may be delayed for hours. The response is not dose related, and one study showed an average drop in MAP of 35% at all doses and a 60% response rate. Although no adverse effects were seen in this study, which excluded patients older than 80 years and with
known renovascular disease, such a significant drop in MAP might exceed the limits of vascular autoregulation in some patients. In fact, azotemia has been reported among older patients in studies of ACE inhibition after MI.\(^{37}\)

Adverse effects seen with ACE inhibitors such as enalapril include idiopathic angioedema, cough, and renal failure. Renal failure has been classically described in patients with bilateral renovascular disease. ACE inhibitors are considered toxic in the first trimester of pregnancy.

### Clinical Presentation and Management of Poorly Controlled Hypertension

Elevated BP without evidence of progressive end-organ involvement does not require urgent treatment in the ED.\(^2\) Historically, these patients, on the basis of arbitrarily defined BP elevations and the ill-conceived term “hypertensive urgency,” were inappropriately treated with antihypertensive agents in the ED with little regard for the chronicity of the condition, potential adverse effects of acutely lowering their BP, or transition to a stable, oral, outpatient regimen for long-term control. It is unnecessary to lower BP acutely in the ED for these patients, and this practice may actually cause increased risk of adverse effects.\(^7,58\) These patients are best managed with a long-term, ambulatory regimen, monitored and adjusted by their primary care provider.

Patients with elevated BP who are asymptomatic or have nonspecific symptoms require a thorough history and physical examination, paying special attention to the cardiovascular, funduscopic, and neurologic systems and findings. Depending on the presentation, laboratory testing may be helpful, including a urinalysis and electrolyte panel to evaluate renal function. In patients without any history of renal disease, a normal urinalysis obviates the need for blood tests of renal function.\(^59\)

A chest radiograph and ECG are obtained to evaluate patients with chest pain or symptoms of cardiac dysfunction. If initial evaluation fails to show any acute end-organ damage and myocardial ischemic symptoms are not present, the patient may be referred for outpatient evaluation within 7 days. Unfortunately, the evaluation for end-organ ischemia and referral for subsequent care occurs in a minority of patients with elevated blood pressures in most EDs.\(^60-62\)

In some patients, it is evident that ongoing chronic pharmacologic therapy is indicated. In the ambulatory setting, the decision to initiate pharmacologic therapy for well-documented hypertension must be based on the degree of hypertension (Tables 82-2 and 82-3). These recommendations are not without controversy.\(^2,63,65\) It is rarely advisable to initiate or substantially modify the outpatient treatment of hypertension in the ED, unless the patient has known (i.e., previously diagnosed and treated) hypertension, and treatment is restarted or modified in close consultation with the primary care provider. Large population-based studies comparing different classes of antihypertensive agents have established the thiazide diuretics, such as hydrochlorothiazide at 25 to 50 mg once a day, as the first-line agent of choice in the absence of compelling indications for other classes of antihypertensives.\(^2,66-68\) These agents are inexpensive, well tolerated, and easy to take. Other more expensive agents have failed to show better efficacy in preventing the cardiovascular complications of hypertension.

Beta-blockers or calcium channel blockers are substituted or added as indicated.\(^2,9,66-70\) Common starting doses of generic beta-blockers include atenolol 25 to 50 mg or metoprolol 50 mg once or twice daily. For patients with other health problems, specific classes of drugs have been shown to be particularly beneficial; the comorbid conditions should guide antihypertensive therapy. For patients with intact left ventricular function and a history of MI, a beta-blocker is the agent of choice. On the basis of evidence of increased mortality, such patients should not be treated with immediate-release dihydropyridine calcium channel blockers.\(^71\) For patients with diabetes, ACE inhibitors or angiotensin receptor blockers (ARBs) have benefits with respect to the preservation of renal function beyond that seen with BP control alone. In diabetic patients as well as in those with a history of left ventricular failure, an ACE inhibitor or an ARB should be the drug of choice. Elderly

</tbody>
</table>
patients with isolated systolic hypertension may benefit from the addition of a long-acting calcium channel blocker when diuretic monotherapy fails. Patients with prostatism or dyslipidemia may benefit from alpha-blocker therapy, although a large prospective trial comparing the thiazide diuretic chlorthalidone with three other types of therapy showed an increased incidence of congestive heart failure and stroke in the group treated with the alpha-blocker doxazosin. Regardless of the agent used, long-term reduction of BP to the target level remains the most important endpoint for the prevention of cerebrovascular, heart, and renal disease.

**Mild or Transient Hypertension**

A vast majority of the hypertension encountered in the ED is either transient or mild. The most common causes of transient hypertension are pain and anxiety. In these patients, end-organ ischemia does not occur, and attention is focused on treatment of the primary process. Patients with incidental hypertension identified during a visit for another purpose should simply be referred to their primary care physicians for repeated measurement in a few days to a few weeks. Most patients, even those with poorly treated chronic hypertension, show an improvement in their BP with watchful waiting.
KEY CONCEPTS

- The presence or absence of acute target organ damage determines whether a hypertensive emergency exists and whether treatment of the BP elevation is indicated in the ED.
- All patients with persistent and marked elevations in BP (e.g., diastolic BP >110 mm Hg or systolic BP > 200 mm Hg) should be carefully evaluated for the presence of acute end-organ ischemia.
- The therapeutic goal for treatment of the majority of hypertensive emergencies is careful reduction of the BP with a titratable agent. Mean arterial pressure should be reduced by no more than 20 to 25% over minutes to hours. The diastolic pressure generally should not fall below 100 to 110 mm Hg. The exceptions to these rules may be patients with hypertensive complications of pregnancy, hypertensive emergencies of the pediatric population, and patients with aortic dissection.
- Patients without acute end-organ ischemia should not receive antihypertensive agents in the ED, and they may be safely referred for outpatient follow-up.

Aortic Dissection

Felix Ankel

Epidemiology
Aortic dissection occurs more often in men and increases with age. The incidence and prevalence are difficult to determine because of underreporting of this condition. Mortality is 1 to 5 per 100,000 population per year. Hypertension is the most common risk factor associated with aortic dissection and is seen in most patients. A history of cardiac surgery is present in about 18% and a bicuspid aortic valve in 14% of all patients with aortic dissections but more often in proximal dissections. Atherosclerosis is rarely involved at the site of dissection. Patients with aortic dissection may have a positive family history.

Aortic dissection is uncommon before age 40 except in association with congenital heart disease, Ehlers-Danlos or Marfan’s syndrome, or giant-cell arteritis. As many as 44% of patients with Marfan’s syndrome develop aortic dissection and account for about 5% of cases. Women with Marfan’s syndrome are at particular risk during pregnancy. In patients without connective tissue disease and with an aortic root size of less than 40 mm, pregnancy does not appear to be an independent risk factor. Acute aortic dissection also occurs with stimulant use, exertion, and trauma. It may also be seen in patients who undergo cardiac surgery or intra-aortic balloon pump insertion.

Blunt trauma from a high-speed deceleration injury usually causes traumatic aortic rupture, which is an entity distinctly different from aortic dissection (see Chapter 42).

Pathophysiology
Medial degeneration, previously thought to be specific for aortic dissection, is now considered to be part of normal aging, although it is augmented by hypertension and with aortic dissection. The anatomic differences between the “normal” aorta and a dissection are quantitative rather than qualitative. The repetitive hydrodynamic forces produced by the ejection of blood into the aorta with each cardiac cycle contribute to weakening of the aortic intima and to medial degeneration. These hydrodynamic forces primarily affect the ascending aorta. Sustained hypertension intensifies these forces and results in an increase in medial degeneration. A bicuspid aortic valve may disrupt laminar flow and reorient the flow of blood toward the aortic wall, producing local injury. In Marfan’s and Ehlers-Danlos syndromes, normal hydrodynamic forces act on an aortic media that is already weakened.

As a result of medial degeneration and repeated flexion of the aorta, hydrodynamic stress tears the aortic intima and a column of blood gains access into the aortic media. An alternative theory suggests that these forces damage the vasa vasorum of the aorta, which rupture and hemorrhage into the aortic media, which may explain the absence of an intimal tear in some cases of dissection. Regardless of which of these theories is correct, the depth of penetration into the media and the distance and direction of dissection are at least partially determined by the degree of medial degeneration.

Once a dissecting hematoma is established in the media, migration of the hematoma occurs in an antegrade or retrograde fashion, or both, forming a “false lumen.” The false lumen forms in the outer half of the media and propagates until it ruptures back into the “true lumen” of the aorta, resulting in a rare “spontaneous cure,” or through the adventitia into the pericardial sac or pleural cavity. Because the outer wall of the aorta that contains the hematoma is thin, rupture is much...
more likely to occur to the outside. The most important factors favoring continued dissection of the aorta are (1) the degree of elevation of blood pressure and (2) the steepness (slope) of the pulse wave (upstroke pattern on apex cardiogram, dP/dt). Both of these hemodynamic factors must be controlled to halt migration of the hematoma.

**Classification**

Anatomic classification is important for diagnosis and therapy. The Stanford classification is based on the involvement of the ascending aorta. Type A dissections involve the ascending aorta; type B dissections do not (Fig. 83-1). Dissections that involve the ascending aorta are much more often lethal than those limited to the distal aorta and call for a different therapeutic approach. In the International Registry of Acute Aortic Dissection (IRAD), 62% of dissections are type A and 38% are type B.24 Patients with distal dissections tend to be older, heavy smokers with chronic lung disease, and more often have generalized atherosclerosis and hypertension compared with patients who have proximal aortic dissections.

Two other aortic conditions are closely related to aortic dissection: intramural hemorrhage19,20 and penetrating aortic ulcer. Both groups of patients have clinical symptoms and management recommendations similar to those for patients with aortic dissection. An intramural hemorrhage is a contained hematoma within the aortic wall and occurs in about 10% of aortic dissections.4 Rupture of the vasa vasorum is believed to be the initial event. Penetrating atherosclerotic ulcers of the aorta occur in older hypertensive patients with evidence of coronary artery disease. Computed tomography (CT) shows a focal ulceration without dissection, most commonly in the distal descending aorta. The progression of penetrating ulcers results in progressive aortic enlargement with saccular and fusiform aneurysm formation. Patients can have both an intramural hematoma and a penetrating atherosclerotic ulcer.21

A dissection is acute if it is of less than 2 weeks’ duration and chronic if present for more than 2 weeks.

**Clinical Features**

**History**

Pain is by far the most common presenting complaint, affecting more than 90% of patients.46,8 Most cases of painless aortic dissection are chronic in nature.7 The pain is usually excruciating, occurs abruptly, is most severe at onset, and is typically described as “sharp” more often than “tearing” or “ripping.” The location of the pain may help localize the dissection. Anterior chest pain is associated with the ascending aorta, neck and jaw pain with the aortic arch, pain in the interscapular area with the descending thoracic aorta, and pain in the lumbar area or abdomen with involvement below the diaphragm. Migration of the pain consistent with propagation of the dissection suggests aortic dissection but occurs in only 17% of cases.7 The onset of aortic dissection is often accompanied by visceral pain symptoms, such as diaphoresis, nausea, vomiting, lightheadedness, and severe apprehension.

Syncope occurs early in aortic dissection in approximately 9% of cases and may be the sole presentation in some patients.4,8 It most often heralds dissection into the pericardium, causing pericardial tamponade, but may occur from transient interruption of blood flow to the cerebral vasculature. Other causes of syncope secondary to aortic dissection are hypovolemia, excessive vagal tone, and cardiac conduction abnormalities. Neurologic symptoms such as focal weakness or change in mental status occur in up to 17% of cases.46,8

**Physical Examination**

The presentation varies greatly, depending on the patient and the location and extent of the dissection. Generally, the patient appears apprehensive. Most of the patients have a history of chronic hypertension that may be exacerbated by a catecholamine release related to the acute event. Severe hypertension refractory to medical therapy may occur if the dissection involves the renal arteries with subsequent renin release. If hypotension is present, either the dissection has progressed back into the pericardium with resulting pericardial tamponade or hypovolemia has occurred from rupture through the adventitia. Pseudohypotension, a condition in which the blood pressure in the arms is low or unobtainable and the central arterial pressure is normal or high, may be present. This results from the interruption of blood flow to the subclavian arteries.

Aortic regurgitation occurs in up to 32% of patients and is more common with type A dissections.46,8 The murmur of aortic insufficiency may have a musical, vibrating quality with variable intensity, and congestive heart failure may develop. The patient with presumed aortic dissection should be examined carefully for findings that suggest hemorrhage into the pericardium or tamponade, such as jugular venous distention, muffled heart sounds, tachycardia, and hypotension.

When the integrity of one of the branches of the aorta is compromised, the expected ischemic findings occur. Pulse deficits and discrepancies in blood pressure between limbs can be helpful if present46,8 but have a sensitivity of only around 30%.22 Usually these are present in the upper extremities and result from involvement of one or both of the subclavian arteries. Obstruction of one or both common iliac or superficial femoral arteries may produce pulse deficits in the lower extremities. Arterial obstruction may occur by either of two mechanisms. An intimal flap produced by the dissection may cover the true lumen of a branch vessel, or the dissecting hematoma may compress an adjacent true lumen. Frequent reexamination may detect transient pulse deficits.

Neurologic findings are related to the site of blood flow interruption. Proximal dissections are a more frequent cause of strokes or coma. Stroke treatment with a fibrinolytic agent in the patient with aortic dissection can be fatal. Distal dissections occluding the anterior spinal artery commonly cause ischemic paraparesis or ischemic peripheral neuropathy.25
In up to 3% of cases, a proximal dissection can dissect into the ostium of a coronary artery, most frequently the right coronary artery, and cause an acute myocardial infarction (MI), usually inferior to posterior. Failure to identify the inciting aortic dissection with incorrect administration of a fibrinolytic agent occurs in about 0.1 to 0.2% of MIs. Distal extension of aortic dissections into the abdomen can cause mesenteric ischemia, renal failure, femoral pulse deficits, and lower extremity ischemia.

**Diagnostic Strategies**

Routine laboratory tests are of little value in the diagnosis of aortic dissection. Unless massive hemorrhage has occurred, the hemoglobin is normal or only modestly reduced. The leukocyte count is commonly mildly elevated. Recently, there has been increasing interest in the biochemical diagnosis of acute aortic dissection. Myocin heavy-chain concentrations, D-dimer levels, and soluble elastin fragments are some of the newer tools that may be helpful to the diagnosis of aortic dissection and await prospective clinical trails to evaluate their usefulness. Historically, aortography was the “gold standard” against which other modalities were measured. With the advent of transesophageal echocardiography (TEE) and CT scanning, however, conventional aortography is rarely used as the initial diagnostic modality and is no longer the imaging modality of choice.

**Electrocardiography**

The electrocardiogram (ECG) is often useful in excluding MI; however, 15% of patients with aortic dissection may have ECG abnormalities suggesting ischemia. Proximal dissections that involve the right coronary artery may show an infarction. No abnormalities are noted on the ECG in 31% of patients, but the abnormalities are nonspecific and rarely diagnostic. Mediastinal widening occurs in the majority of cases; may occur in the ascending aorta, aortic arch, or the descending portion of the thoracic aorta; and may be difficult to differentiate from the aortic tortuosity that is associated with chronic hypertension. A plain chest radiograph is inadequate for ruling out aortic dissection. Up to 12% of patients with aortic dissection have a normal chest radiograph (see Table 83-1).

The “calcium sign” is an uncommon radiographic manifestation of aortic dissection. Ordinarily, when intimal calcification is visible on a radiograph, it is butted up against the outer border of the aorta. With dissection of the aortic media, the calcium deposit becomes separated from the outermost portion of the aorta by more than 5 mm.

Other helpful radiographic signs include a double-density appearance of the aorta suggesting true and false channels, a localized bulge along a normally smooth aortic contour, a disparity in the caliber between the descending and ascending aorta, obliteration of the aortic knob, and displacement of the trachea or nasogastric tube to the right by the dissection. Previous chest roentgenograms, when available, are useful for comparison.

**Echocardiography**

Transthoracic echocardiography (TTE) is an insensitive tool for detecting aortic dissection because it does not visualize the aortic arch or much of the descending aorta, and imaging quality may not be optimal because of the patient’s body habitus. While more sensitive imaging tests are being scheduled, however, TTE can provide valuable information about pericardial effusion or aortic regurgitation and can help determine whether cardiac tamponade is the cause of hypotension in a patient with aortic dissection.

Transesophageal echocardiography (TEE) is highly sensitive (Table 83-2) in the diagnosis of aortic dissection. The proximity of the esophagus to the aorta and the ability to use higher transducer frequencies help to visualize the entire aorta and to detect pericardial effusion and aortic regurgitation. TEE can be quickly performed at the patient’s bedside with sedation or light anesthesia and requires no radiation or contrast.
agent injection. Visualization of the distal ascending aorta and proximal arch used to be difficult because of the interposition of the air-filled trachea and left mainstem bronchus, but evaluation of this “blind spot” has been aided by biplane and multiplane probes. The diagnostic accuracy of TEE depends on the experience and availability of the echocardiographer. It is the primary diagnostic method in many institutions for detecting aortic dissection and is the procedure of choice in unstable patients, in whom it can be done in the resuscitation area of the ED, or in the operating room coincident with induction of anesthesia.

Computed Tomography

CT aortography is a reliable test for diagnosing aortic dissection (see Table 83-2) and is the diagnostic test of choice in most institutions. Findings suggestive of aortic dissection include dilatation of the aorta, identification of an intimal flap, and the clear demonstration of both the false and true lumina (Fig. 83-2). Dynamic scanning, in which rapid scans are obtained at multiple levels immediately after a bolus injection of an intravenous (IV) contrast agent, improves the accuracy of the CT scan in the diagnosis of aortic dissection by allowing detection of differential filling rates in the true and false lumina (see Fig. 83-1). Dynamic scanning performed with helical CT improves sensitivity and specificity. Sixty-four-slice multidetector computed tomography (MDCT) may soon alter the approach to chest pain in the emergency department (ED). MDCT may reliably evaluate for coronary artery disease, pulmonary embolus, and aortic dissection as a “triple” scan.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is an appealing option in the detection of low-grade aortic dissection in stable patients in whom the diagnosis is uncertain. Sensitivity and specificity are excellent (see Table 83-2). MRI shows the site of intimal tear, type and extent of dissection, presence of aortic insufficiency, and differential flow velocities in the true and false channels and in the aortic side branches. It requires no contrast material or ionizing radiation and is noninvasive. It is particularly useful in the evaluation of chronic aortic dissection, in the follow-up of postoperative patients, and for monitoring nonoperative patients for progression of the dissection. Its availability, however, is limited and it is difficult to perform in unstable patients.

Choice of Diagnostic Test

Although aortic dissection can be suggested on the basis of history and physical examination, diagnostic imaging is necessary to establish the diagnosis. With a mortality rate in excess of 1% per hour after the onset of aortic dissection, a diagnostic study should be performed as soon as possible. Frequently, more than one test is required to diagnose the condition and to assess associated complications.

The clinical services within the hospital involved in the diagnosis and treatment of aortic dissection should prospectively agree on a strategy. This strategy should consider (1) the technology available at the institution, (2) the institution-specific sensitivities and specificities for the diagnostic tests, (3) the benefits of diagnosing nondissecting causes of chest pain, and (4) the ease of obtaining each test, especially “after hours.” Some tests (e.g., CT, MRI, aortography) may require moving a potentially unstable patient outside the ED. In IRAD, the initial choice of diagnostic test was CT in 61%, TTE or TEE in 33%, aortography in 4%, and MRI in 2% of patients. “Real-world” sensitivities of diagnostic tests in IRAD were CT 93%, TEE 88%, aortography 87%, and MRI 100%; and patients averaged 1.85 imaging studies. A recent meta-analysis suggests that TEE, helical CT, and MRI yield similar diagnostic value in ruling aortic dissection in or out.

Differential Considerations

The differential diagnosis for the patient with symptoms suggestive of aortic dissection is extensive. Signs and symptoms associated with aortic dissection vary and depend on the extent of aortic and branch vessel involvement. Patients with the ultimate diagnosis of aortic dissection are often initially thought to have other conditions such as myocardial ischemia, congestive heart failure, or pulmonary embolus. Several clinical syndromes are particularly suggestive of aortic dissection: sudden-onset chest pain, migratory pain, chest pain with concomitant neurologic deficits or syncope, and chest pain with pulse deficits.

Although chest pain is the most common symptom of aortic dissection, it is also the most common presenting complaint of at least three other serious and more common clinical entities: acute MI, pulmonary embolus, and pericarditis. An ECG can be helpful in excluding MI, although aortic dissection and MI may coexist as a result of the dissection proceeding retrograde to the ostium of a coronary artery and causing infarction. In cases in which aortic dissection is excluded, CT may reveal other abnormalities that explain a patient’s presentation (e.g., pulmonary embolus). TEE is helpful in identifying etiologies of chest pain other than aortic dissection (e.g., cardiac ischemia).

When the initial presentation of the aortic dissection is pain or dysfunction in an extremity resulting from disruption of the blood supply, peripheral neurologic diagnoses should be included in the differential diagnosis. An aortic dissection may involve the carotid artery with the initial presentation mimicking that of a primary central nervous system lesion such as a stroke. The diagnosis of aortic dissection should be entertained in any patient with a new diagnosis of pericardial effusion, pericardial tamponade, or aortic insufficiency.
Emergency Department

Early therapy for aortic dissection is critical and should be initiated while diagnostic tests are being performed. Opioids should be administered in adequate amounts to control pain and decrease sympathetic tone. Patients with aortic dissections are typically hypertensive. The two goals of medical management are to (1) reduce blood pressure and (2) decrease the rate of rise of the arterial pulse (dP/dt) to diminish shearing forces.

A target blood pressure of 100 to 120 mm Hg systolic and a heart rate less than 60 beats/min are recommended. Beta-adrenergic blockers are the cornerstone of aortic dissection management. Because vasodilators such as sodium nitroprusside or fenoldopam reflexively increase the heart rate and may also increase the dP/dt, a beta-blocker must be started before or in conjunction with vasodilator therapy to lower the dP/dt.

Esmolol is an ultrashort-acting beta-blocker that is easily titrated. After mixing 5 g in 500 mL of 5% dextrose in water (D,W), an initial bolus of 500 µg/kg is given, followed by an infusion of 50 to 200 µg/kg/min. Labetalol has both alpha- and beta-blocking activity and can be used as monotherapy. A suggested dose is an initial 20-mg IV bolus every 5 to 10 minutes, incrementally increased to 80 mg IV until a target heart rate is reached or a total of 300 mg is given. A maintenance infusion of labetalol is then given at 1 to 2 mg/min. If a patient is normotensive, a beta-blocker should still be used to lower the dP/dt. In patients with a history of chronic obstructive pulmonary disease or at risk for bronchospasm, a selective beta-blocker such as metoprolol or atenolol should be considered.

Sodium nitroprusside can be used, in conjunction with a beta-blocker, to maintain the systolic blood pressure at 100 to 120 mm Hg or to the lowest level to maintain vital organ perfusion. Nitroprusside, 50 mg, is mixed in 500 mL of D,W and initially infused at a rate of 0.5 to 3 µg/kg/min.

The calcium channel blocker nifedipine is not recommended to treat aortic dissection. Nifedipine has minimal inotropic and chronotropic effects and may reflexively stimulate sympathetic activity and increase shear stress on the aortic wall. IV nitroglycerin is often used initially in patients with hypertensive chest pain and possible or uncertain aortic dissection. Nitroglycerin is a less effective arterial dilator than nitroprusside and less desirable than nitroprusside for the treatment of patients with aortic dissection. Nitroglycerin must, like nitroprusside, be accompanied by a beta-blocker. Some physicians prefer an infusion of fenoldopam over nitroprusside, but this has not been specifically studied in patients with aortic dissection.

Patients presenting with hypotension secondary to aortic rupture or pericardial tamponade should be resuscitated with IV fluids and immediately transported to the operating room if they are to have a chance to survive. Blood pressure should be measured in all four limbs, if necessary, to ensure that this is not a pseudohypotension caused by an intimal flap obstructing the extremity in which the blood pressure is measured. In patients with electromechanical dissociation or marked hypotension, pericardiocentesis may raise the blood pressure while awaiting definitive surgery.

Surgery

Type A acute aortic dissections require prompt surgical treatment. The aortic segment containing the original intimal tear is resected when possible, with graft replacement of the ascending aorta to redirect blood into the true lumen. If aortic insufficiency is present, it can be corrected through aortic valve resuspension or replacement. Patients with type A dissections have an in-hospital mortality rate of 27% when treated surgically versus an in-hospital mortality of 56% when treated medically.

Definitive treatment of type B acute aortic dissections is less clear. These patients in general tend to be worse surgical risks. Uncomplicated distal dissections have traditionally been treated with blood pressure control, and patients have an in-hospital mortality of 10% when treated in this manner. Surgery has been reserved for patients who have persistent pain, uncontrolled hypertension, occlusion of a major arterial trunk, frank aortic leaking or rupture, or development of a localized aneurysm. These patients have an in-hospital, 30-day mortality rate of 32%. A “deadly triad” of absence of chest pain, hypotension, and branch vessel involvement is an independent predictor of in-hospital death.

Interventional Therapy

In general, interventional endovascular techniques are not applicable to type A dissections. Interventional stent-graft and fenestration techniques are replacing surgery for complicated type B dissections in some centers, especially for patients with renal and mesenteric ischemia. Patients treated with interventional therapy have an in-hospital mortality rate of 6.5%. Interventional therapy for stable type B dissections is currently under study, and treatment decisions should rest with the primary treating physician.

DISPOSITION

Patients who present with chronic aortic dissection have already survived their period of greatest mortality risk and are usually treated by blood pressure control and close monitoring unless complications mandate surgery. All patients who have sustained and survived an aortic dissection, regardless of the type of definitive therapy used, require careful long-term treatment. Major complications that may occur with time are re-dissection, the development of a localized aneurysm, and progressive aortic insufficiency.

KEY CONCEPTS

- Risk factors for aortic dissection include advanced age, hypertension, and connective tissue disorders such as Marfan’s or Ehlers-Danlos syndrome.
- Most patients with aortic dissection have chest pain, described as sudden-onset, sharp, and migratory. Chest pain associated with neurologic symptoms or syncope should increase the possibility of aortic disease.
- Physical examination findings may include pulse deficit, aortic insufficiency murmur, or neurologic findings.
- Diagnosis is difficult using only history, physical examination, and chest radiography. Computed tomography and transesophageal echocardiography are the confirmatory tests used most often.
- Treatment of type A proximal dissection is surgical. Treatment of uncomplicated type B distal dissection is usually medical, with a beta-blocker and nitroprusside to control blood pressure and dP/dt shearing forces. These agents are also used to control blood pressure and pulse in the preoperative phase for hypertensive patients with type A dissection.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
The abdominal aortic aneurysm (AAA) should be distinguished from other abnormalities of the aorta. Most AAAs are true aneurysms. A true aortic aneurysm is a localized dilatation of the aorta caused by weakening of its wall; it involves all three layers (intima, media, and adventitia) of the arterial wall (Fig. 84-1). AAAs should not be confused with aortic dissections, which are sometimes incorrectly called “dissecting aortic aneurysms.” In aortic dissection, blood enters the media of the aorta and splits (dissects) the aortic wall (see Chapter 83). True aortic aneurysms and aortic dissections are very different diseases, with different clinical presentations, complications, diagnostic methods, and treatments.

A pseudoaneurysm (false aneurysm) is a collection of flowing blood that communicates with the arterial lumen but is not enclosed by the normal vessel wall; it is contained only by the adventitia or surrounding soft tissue. Pseudoaneurysms can arise from a defect in the arterial wall or a leaking anastomosis after AAA repair.

Aneurysms can develop in any segment of the aorta, but most involve the aorta below the renal arteries. The diameter of the normal adult infrarenal aorta is approximately 2 cm, and a diameter of 3 cm or more defines an AAA.

Epidemiology

An AAA is a disease of aging, and the number of AAAs is expected to increase as the population of elderly patients grows. AAAs are rare before the age of 50 years but are found in 2 to 5% of men older than 50. The average age at the time of diagnosis is 65 to 70, and men are affected much more often than women. The patient often has atherosclerotic occlusive disease involving the coronary, carotid, or peripheral vessels, which may influence the clinical presentations, complications, and management.

Certain groups are at greatest risk for AAAs (Table 84-1). An AAA can be found in 5 to 10% of elderly men who are screened with ultrasonography and in an even higher percentage of patients with coronary artery disease or peripheral vascular disease. A family history of an AAA is a very strong risk factor; those with an affected first-degree relative have a 10- to 20-fold increased risk of developing an AAA. Awareness of these high-risk groups can speed the recognition of AAAs in these patients.

Pathophysiology

AAAs have traditionally been attributed to atherosclerosis, but other factors probably contribute to their formation. Most patients with advanced atherosclerosis have occlusive disease, not aneurysms. Biochemical abnormalities leading to the loss of elastin and collagen, the major structural components of the aortic wall, have been identified in patients with AAAs. The propensity to form aneurysms may have a genetic basis, but the exact mode of inheritance is uncertain. The Society for Vascular Surgery has recommended labeling the typical degenerative AAA as “nonspecific,” rather than “atherosclerotic,” to reflect this uncertain cause.

AAAs sometimes result from specific causes, such as infection, trauma, connective tissue diseases, and arteritis. Such aneurysms are rare compared with nonspecific, degenerative aneurysms.

Natural History

AAAs progressively enlarge, ultimately resulting in rupture of the aneurysm and fatal hemorrhage. Although other potential complications are possible, by far the most common and most important is rupture. The most important factor determining the risk of rupture is the size of the aneurysm. The rupture risk increases dramatically with increased aneurysm size, and most ruptured AAAs have diameters greater than 5 cm. Although rupture of aneurysms smaller than 4 cm is rare, no aneurysm is completely “safe.” Any aneurysm can rupture and may be the source of the symptoms causing the patient’s emergency department (ED) presentation.

Rupture of an AAA usually occurs into the retroperitoneum, where hemorrhage may be temporarily limited by clotting and tamponade at the rupture site. Of patients with ruptures, 10 to 30% have free intraperitoneal rupture, which is often rapidly fatal. Occasionally, rupture occurs into the gastrointestinal tract or the inferior vena cava.

Complications can also arise from intact AAAs. The walls of AAAs are often lined with clot and atheromatous material, which can embolize and occlude distal vessels. Aortic thrombosis may occur rarely. Patients can also have complications caused by impingement on adjacent structures.
In approximately 5% of AAAs, a dense inflammatory and fibrotic reaction develops in the aneurysm wall and adjacent retroperitoneal tissue. In these “inflammatory” AAAs, the periaortic fibrosis may incorporate and obstruct adjacent structures, such as the ureters.21,22

The overwhelming concern in the patient with an AAA is the potential for rupture of the aneurysm. The natural history of expansion and rupture can be interrupted only by timely repair.

### CLINICAL FEATURES

#### Unruptured Aneurysms

Because most AAAs cause no symptoms until they rupture, the prevalence of symptoms in patients with unruptured AAAs is unknown. Patients may have symptoms, such as pain in the abdomen, back, or flank; an awareness of an abdominal mass or fullness; or a sensation of abdominal pulsations, that lead to the aneurysm’s discovery.9,11,23 The pain associated with stable, intact aneurysms has a gradual onset and a vague, dull quality. It is usually constant but may be described as throbbing or colicky. Acute or severe pain is an ominous symptom that suggests imminent or actual aortic rupture.2

In many cases, an AAA is discovered incidentally on physical examination, on a radiologic study done for other reasons, or in an ultrasonography aneurysm screening program.22,23 Symptoms usually do not develop until the aneurysm ruptures.

The most consistent physical finding is a pulsatile, expansile abdominal mass. The aortic bifurcation is at the level of the umbilicus, and an AAA can be palpated at or above this level. The mass may extend below the umbilicus if the iliac arteries are involved. The right border of an AAA may be palpable to the right of midline, whereas a normal or tortuous aorta is usually not. Most intact AAAs are nontender; tenderness suggests aneurysm expansion or rupture.9

Symptomatic aneurysms are usually fairly large and are often palpable. Likewise, the patient with an aneurysm large enough to warrant elective repair often has a palpable abdominal mass.9,11,24 However, an AAA may be difficult to palpate if the aneurysm is small or the patient is obese. Published reports indicate that 30 to 60% of nonruptured aneurysms measuring 3.0 to 3.9 cm by ultrasonography can be detected by abdominal palpation; 50 to 70% of aneurysms measuring 4.0 to 4.9 cm and 75 to 85% of aneurysms 5 cm or larger can be palpated.11,24 These reports are based on the examination of patients with intact, largely asymptomatic aneurysms, with the exam specifically directed at sizing the aorta. The sensitivity is likely much lower when the abdomen is not palpated deeply, and in hypotensive patients or those with significant abdominal guarding. There is virtually no risk of causing aneurysm rupture by abdominal palpation.11

When the physical examination is suggestive of an AAA, the aorta is often still of normal size.1 A tortuous aorta may feel enlarged, and prominent aortic pulsations may simulate an aneurysm, especially in a thin patient. Aortic pulsations may be transmitted to an adjacent mass. Nonetheless, clinical suggestion of an AAA warrants further investigation.

An abdominal bruit is found in only 5 to 10% of patients with AAAs.9 The presence of a bruit is a nonspecific finding because bruits can also originate in a stenotic renal, iliac, or mesenteric artery. A loud continuous bruit suggests the diagnosis of aortovenous fistula.25

Perfusion distal to an AAA is usually well maintained, and most patients have normal femoral pulses.2 Diminished femoral pulses may result from iliofemoral occlusive disease or from hypotension in the patient with a ruptured aneurysm.

Thromboembolic complications can occur spontaneously or when atheromatous plaques are disrupted during invasive intravascular procedures. Large emboli can acutely occlude major vessels such as the iliac, femoral, or popliteal artery, causing acute painful lower extremity ischemia with absent distal pulses. Rarely, the aneurysm itself can thrombose, rendering both lower extremities acutely ischemic.

More often, microemboli consisting of cholesterol crystals or clot obstruct small distal vessels, such as the digital arteries of the toes and arterioles and capillaries of the skin. These patients have livedo reticularis; one or more cool, painful, cyanotic toes; and palpable pedal pulses.20 This constellation of findings, often called the “blue toe” syndrome, is highly suggestive of a proximal source of emboli. When an AAA is the source, the aneurysm is often too small to palpate and may be discovered only after radiologic investigation.20

Rarely, an intact AAA causes atypical symptoms by compressing adjacent structures.2 Large, long-standing aneurysms can cause vertebral body erosion and severe back pain. Compression of the duodenum between the superior mesenteric artery and an AAA can cause duodenal obstruction, vomiting, and weight loss.26 Obstruction of the ureters in the patient with an inflammmatory aneurysm can cause ureteral colic.21,22

#### Ruptured Aneurysms

##### Pain-Hypotension-Mass Triad

Although the classic triad of a ruptured AAA is pain, hypotension, and a pulsatile abdominal mass,2 many patients have only one or two components of this triad, and an occasional patient has none of the classic features.

Rupture is often the first manifestation of an AAA. Some patients, however, have a previously diagnosed AAA, and a decision not to operate electively may have been made because the aneurysm was small or the patient was considered to be at too high a risk. If such a patient has acute symptoms, the presumptive diagnosis is aneurysm rupture.

Most patients with a ruptured AAA experience pain in the abdomen, back, or flank. Pain is usually acute, severe, and constant and can radiate to the chest, thigh, inguinal area, or scrotum. The history of pain may be unobtainable if the patient’s mental status is compromised by severe hypotension.

The mechanism of the pain associated with aneurysm rupture is poorly understood. It may be caused by expansion of the aortic wall or by stimulation of sensory nerves in the retroperitoneum. Identical pain can occur with intact but acutely expanding aneurysms, which may be impossible to differentiate clinically from ruptured aneurysms. Acute pain in the patient with an AAA should be considered a symptom of rupture or impending rupture.

The duration of symptoms before presentation varies greatly. Some patients are seen shortly after severe pain and hypotension develop. In others, rupture is initially contained in the retroperitoneum, blood loss is small, and the presentation is delayed, sometimes for several days or even weeks. A long duration of symptoms does not exclude the diagnosis of ruptured AAA.

Rupture of an AAA may be accompanied by nausea and vomiting, and sudden hemorrhage can cause syncope or near-syncope. Compensatory hemodynamic mechanisms may then return the blood pressure and cerebral perfusion to normal. Transient improvement in symptoms is fairly common but will be followed by hemodynamic deterioration if diagnosis and treatment are delayed.

Ruptured AAAs are often large, and most patients have palpable abdominal masses. As with intact aneurysms, a ruptured AAA may not be palpable if the aneurysm is small or the patient is obese. The examination may be difficult if abdominal guarding is present or if an ileus causes significant distention. Aortic pulsations may not be prominent if the blood pressure is low.

Hypotension is the least consistent part of the triad, occurring in only one third to two thirds of patients, and is often a late finding. When the initial blood loss is minor, vital signs are often normal. The patient with initially normal vital signs may deteriorate and become hypotensive suddenly and unpredictably.

Occasionally, rupture into the retroperitoneum is sealed and contained for many weeks or months. Patients with this condition develop abdominal or back pain, presumably at the time of aneurysm leakage, that subsequently diminishes or resolves completely. If the diagnosis is made, evidence of chronic rupture (organized hematoma) is found at surgery. These patients can have chronic pain and may progress to free rupture and subsequent massive hemorrhage at any time.

**Aortoenteric Fistula**

An AAA can rupture into the gastrointestinal tract (aortoenteric fistula) or inferior vena cava (aortocaval fistula). A primary aortoenteric fistula (AEF) is formed when an unoperated AAA erodes into the gastrointestinal tract, usually the third or fourth portion of the duodenum. A secondary AEF, a communication between the site of previous aortic surgery and the gastrointestinal tract, can occur as a late complication of AAA repair and should be considered as the leading diagnosis in any patient who presents with a severe gastrointestinal bleed and a history of aortic graft placement (see also Chapter 22).

Early in the formation of a primary AEF, the bowel wall is eroded from the outside by the adjacent AAA. This can lead to the leakage of intestinal contents, with local infection and sometimes abscess formation. Eventually, breakdown of the aortic wall leads to an AEF and gastrointestinal bleeding.

The patient with an AEF may have abdominal or back pain, fever or other signs of intra-abdominal infection, or gastrointestinal bleeding. Because most of these fistulas are into the duodenum, hemorrhage usually manifests as hematemesis or melena. The initial bleeding results from erosion of vessels in the bowel wall and is often minor. Later, often after several days to a week or longer, massive bleeding results from rupture into the intestinal lumen.

The possibility of a primary AEF should be considered in any patient older than 50 years with unexplained gastrointestinal bleeding. If an AAA is diagnosed by history, physical examination, or any other modality, the patient should be presumed to have an AEF until proven otherwise.

**Aortovenous (Aortocaval) Fistula**

An aortovenous (usually aortocaval) fistula arises when periarteric inflammation causes adherence of the aorta to an adjacent vein, with pressure on the vessel walls causing the development of an arteriovenous communication. If concomitant extravasation of blood into the retroperitoneum occurs, the clinical presentation is similar to that of other patients with ruptured AAAs, often with hypovolemic shock. More often the aneurysm ruptures into the vena cava without leaking externally, and the signs and symptoms of a large arteriovenous fistula dominate the clinical picture. As in other patients with AAAs, a patient with an aortovenous fistula may have abdominal or back pain. An aneurysm that becomes fistulous with the vena cava is usually large, and 80 to 90% are palpable. A continuous abdominal bruit can be auscultated in approximately 75% of patients with aortovenous fistulas, and 25% of patients have a palpable abdominal thrill.

Shunting of blood from the arterial to the venous system increases venous pressure, venous volume, and venous return to the heart. Signs and symptoms of high-output congestive heart failure (dyspnea, jugular venous distention, pulmonary edema) are often present. The increased venous volume and pressure can cause lower extremity edema or cyanosis, and dilated superficial veins can be seen on the legs or abdominal wall. Distention and rupture of veins in the bladder mucosa can cause gross or microscopic hematuria, and rectal bleeding can occur for similar reasons. Because of shunting of arterial blood into the venous system, the lower extremities may be cool with diminished pulses.

The patient with an aortovenous fistula often has renal insufficiency caused by the decreased renal perfusion that accompanies high-output congestive heart failure and by increased renal venous pressure. Hematuria in these patients may originate from the kidneys or the bladder. Hematuria is common with an aortovenous fistula but not in other patients with AAAs. With an AAA and hematuria, computed tomography (CT, preferably with CT angiography) can rule out aortovenous fistula formation.

### Diagnostic Strategies

#### Abdominal Radiography

Because of its low sensitivity compared with CT and ultrasound, plain abdominal radiography should rarely be used to investigate possible AAA—a normal plain film does not exclude the presence of an AAA and rarely identifies alternative pathology. However, symptomatic aneurysms are usually large and often calcified, and radiographs obtained to investigate other causes of pain (e.g., bowel obstruction or back pain) may reveal signs of an AAA. The most common findings are curvilinear
calcification of the aortic wall (Fig. 84-2) or a paravertebral soft tissue mass.

AAAs can be seen on both anteroposterior and lateral radiographs. In many cases, enough calcium is present in both lateral walls (on an anteroposterior view) or in the anterior and posterior walls (on a lateral view) to measure the aortic diameter and diagnose the presence of an aneurysm. Because the right border of the aneurysm may overlie the spine on the anteroposterior view, the lateral lumbar spine film is often the easiest to evaluate. If only the anterior wall is calcified (on the lateral view), the distance from the anterior wall calcification to the front of the vertebral bodies correlates well with the true aortic size.

**Ultrasonography**

Ultrasonography is virtually 100% sensitive in detecting AAAs (Fig. 84-3), provided that a technically adequate study can be obtained. Measurements of aortic diameter are very accurate and reproducible. Because it is relatively inexpensive and requires no contrast agents or radiation exposure, ultrasonography is often chosen for nonemergency aneurysm diagnosis and used to follow patients with known aneurysms.

Ultrasonography has distinct advantages in the emergency evaluation of a patient with a possible ruptured AAA. It can be performed very rapidly at the patient’s bedside, obviating the need to take a potentially unstable patient to the radiology suite. If an aorta has a normal diameter visualized throughout its abdominal course, the patient does not have an AAA. Ultrasonography sometimes provides alternative explanations for the patient’s pain by revealing conditions such as acute cholecystitis.

Ultrasonography is more operator-dependent than other diagnostic modalities and may be prone to technical or interpretive error. Even with elective studies, the aorta is sometimes not well visualized because of obesity or excess bowel gas. If bedside ultrasonography is not immediately available, waiting for a radiologist or technologist is required. Importantly, although ultrasonography is extremely sensitive in demonstrating the presence of an AAA, it cannot be relied on to determine whether an AAA has ruptured.

Rupture can be confirmed if free intraperitoneal or retroperitoneal blood is seen in the presence of an AAA. However, the sensitivity of emergency ultrasonography in detecting extraluminal blood is very low. The purpose of the study is to confirm or exclude the presence of an aneurysm; clinical information (or CT) must be used to determine the likelihood of rupture. Ultrasonography with the use of contrast agents may aid in the detection of leaking blood, but the clinical utility of this modality remains to be determined. If ultrasonography reveals an AAA in an unstable patient, aneurysm rupture is presumed, and the patient requires immediate aneurysm repair.

**Computed Tomography**

As with ultrasonography, abdominal CT is virtually 100% accurate in determining the presence or absence of an AAA and provides accurate measurements of the aortic diameter. CT is less subject to technical problems and interpretation errors than ultrasonography and is much more sensitive in detecting extraluminal blood. CT is often used to help plan elective procedures because it can provide detailed anatomic information about the aneurysm.
An intravenous (IV) contrast agent is usually administered in elective studies and is desirable, but not essential, in emergency situations.\textsuperscript{42,43,46} With prolonged hypotension, it may be advisable to avoid IV contrast to prevent contrast-exacerbated nephropathy. An IV contrast agent will opacify the aortic lumen and distinguish the patent lumen from mural thrombus. It can demonstrate periarterial fibrosis because the soft tissue surrounding an inflammatory AAA is often enhanced.\textsuperscript{44} IV contrast is not necessary to identify the aneurysm, however, and acute hemorrhage is well visualized on scans done without contrast.\textsuperscript{42,43,46}

When evaluating a patient with a suspected ruptured AAA, a normal aortic diameter on CT excludes an AAA as the cause of the patient’s symptoms. CT provides more information than ultrasonography about other retroperitoneal or intraperitoneal disorders and may reveal diagnoses such as ureterolithiasis, pancreatitis, or diverticulitis. However, CT takes longer than ultrasonography and requires moving the patient out of the ED. Therefore, obtaining CT is appropriate only in hemodynamically stable patients.

CT is much more sensitive than ultrasonography in detecting the retroperitoneal hemorrhage associated with aneurysm rupture. The reported sensitivity ranges from 77 to 100%,\textsuperscript{47} and is probably close to 100% with the use of current-generation scanning technology. Blood is seen as a retroperitoneal fluid collection adjacent to the aneurysm, often tracking into the perinephric space or along the psoas muscle (Fig. 84-4).

Although CT is sensitive in detecting retroperitoneal blood, the results are sometimes falsely reassuring. In these cases, an aneurysm is not seen on the CT scan, without evidence of hemorrhage, but hemodynamic deterioration occurs a short time later, and a ruptured aneurysm is found at surgery. This situation can occur if hemorrhage is missed on the CT scan, or if rupture occurs shortly after the scan is completed. Although CT sometimes reveals signs of impending aneurysm rupture,\textsuperscript{45,48} it cannot reliably determine whether an AAA is the cause of the patient’s pain or whether rupture of the aneurysm is imminent.\textsuperscript{49} Another cause of pain can be diagnosed only if the CT scan shows no aneurysm or shows an intact aneurysm and clearly demonstrates an alternative explanation for the patient’s symptoms.

### Other Diagnostic Modalities

Conventional angiography has virtually no place in the emergency evaluation of the possible ruptured AAA. Because contrast opacifies only the patent lumen and not the mural thrombus, angiography often underestimates aneurysm size and can miss the aneurysm entirely.\textsuperscript{42} In addition, angiography is time-consuming and performed away from the ED. If detailed information is needed about the anatomy of the aneurysm or its relationship to nearby vessels, a CT angiogram can provide the needed information.\textsuperscript{23,43,50}

Magnetic resonance imaging and magnetic resonance angiography can be used for elective preoperative assessment, but not for the evaluation of possible aortic rupture. These procedures are very time-consuming, and the necessary monitoring equipment often cannot be used.\textsuperscript{43}

### DIFFERENTIAL CONSIDERATIONS

Because the patient with a ruptured AAA usually has abdominal, back, or flank pain, with or without hypotension, common misdiagnoses are other disease processes causing these symptoms (Box 84-1). The sudden onset of back pain often leads to the clinical suspicion of renal colic, with which AAA is often confused.\textsuperscript{50} If a suspected kidney stone is investigated by CT, the abdominal aorta should always be evaluated. Abdominal pain and tenderness can suggest pancreatitis, intestinal ischemia, or other intra-abdominal disorders. The diagnosis of musculoskeletal back pain is especially dangerous because these patients are often discharged from the ED.

Epigastric pain and hypotension may lead to an admission diagnosis of acute myocardial infarction. Because the patient with a ruptured AAA often has coexistent coronary artery disease, blood loss from a ruptured aneurysm may diminish coronary perfusion and cause chest pain or electrocardiographic changes consistent with cardiac ischemia. These findings do not rule out the presence of a ruptured AAA.

To avoid missing the diagnosis, a ruptured AAA should be considered in middle-aged or elderly patients who show any part of the classic triad. The diagnosis of ruptured AAA should also be considered when making the diagnoses listed in Box 84-1, especially when the diagnosis is not clear-cut or the patient is at high risk for an AAA.

### MANAGEMENT

#### Ruptured Aneurysms

The patient with a ruptured AAA is unstable until the aorta is cross-clamped in the operating room or stabilized with endo-

---

- Appendicitis
- Perforated viscus
- Bowel obstruction
- Musculoskeletal back pain
- Acute myocardial infarction
vascular techniques. No patient with a known or suspected aortic rupture should be considered “stable,” regardless of the initial vital signs or initial hemoglobin level. Patients taken to the operating room soon after arrival in the ED have a much higher survival rate than those for whom surgical care is delayed.

When the patient arrives at the ED, large-bore IV access should be established and blood sent for crossmatching. Because patients with ruptured AAAs often have large transfusion requirements, at least 6 U of blood should be made available initially, with notification to the blood bank of the potential need for significantly more.\(^\text{18}\) The surgical and anesthesia team should be notified immediately. Further management depends on the patient’s current hemodynamic condition and the level of diagnostic certainty.

The hemodynamically unstable patient in whom a ruptured AAA has been diagnosed or is strongly suspected should be taken to the operating room as soon as possible (in this chapter, the term “operating room” includes other locations that may be used for endovascular aneurysm repair). Diagnostic testing should be kept to a minimum. The diagnosis can often be made from the clinical presentation and abdominal examination, and bedside ultrasonography can quickly confirm or exclude the presence of an aneurysm. CT is appropriate only if it can be obtained very quickly without compromising the patient’s care. Time-consuming tests inappropriately delay definitive therapy and increase the risk of exsanguination. Hypotensive patients may have to be taken to the operating room based on a strong clinical presumption of the diagnosis, without definitive diagnostic imaging. Some of these patients will not have ruptured aneurysms, but they usually have other acute abdominal conditions requiring laparotomy.\(^\text{32}\)

Attempts to resuscitate these patients fully in the ED and normalize the vital signs should be avoided. Hypotensive patients need to be taken to the operating room so that the aorta can be clamped or occluded with a balloon and hemorrhage stopped. If transfer is required, it should be initiated as soon as the diagnosis is known or strongly suspected. Attempts to stabilize the patient in the ED are often fruitless and waste valuable time.

Fluid Resuscitation

The appropriate degree of preoperative volume resuscitation is controversial. Preoperative hypotension is the strongest predictor of mortality in the patient with a ruptured AAA.\(^\text{18,19,53}\) However, correcting the hypotension before clamping the aorta may not improve mortality rates and may even be harmful.

It has been argued that hypotension slows bleeding in patients with AAA and allows clot formation and tamponade of the rupture site. Raising the intravascular volume and blood pressure before occluding the aorta may dislodge clots and cause further bleeding.\(^\text{54}\) Large volumes of crystalloid solution may contribute to bleeding by causing a dilutional coagulopathy. These concerns are similar to those in trauma patients with uncontrolled hemorrhage.

Alternatively, delaying resuscitation of hypotensive patients until they reach the operating room may have deleterious effects. The patient with a ruptured AAA often survives the surgery but dies in the early postoperative period. These deaths are caused by complications of prolonged hypotension, such as myocardial infarction, respiratory failure, and renal failure. The patient with a ruptured AAA is usually elderly, often has coexisting conditions, and tolerates hypovolemia and hypotension poorly.

No prospective studies have compared different preoperative fluid regimens in hypotensive patients with ruptured AAAs, and the optimal resuscitation strategy has not been determined. The priority in these patients is expeditious transportation to the operating room for definitive control of aortic hemorrhage. In the out-of-hospital setting and in the ED before the availability of the surgeon and the operating room, the blood pressure should be raised with crystalloid or blood products only to a level that maintains adequate cerebral and myocardial perfusion. The goal is to prevent irreversible end-organ damage. An arbitrary blood pressure goal cannot be specified because the blood pressure necessary for vital organ perfusion varies among patients, but a reasonable target is a systolic blood pressure of 80 to 100 mm Hg.

Endovascular Approach

Until recently, ruptured AAAs were repaired almost exclusively via open surgical techniques. Endovascular repair of ruptured aneurysms is now feasible, even in unstable patients.\(^\text{50,55,56}\) If necessary, the surgeon can stabilize the patient by placing an aortic occlusion balloon above the aneurysm after rapidly accessing the femoral artery. However, not all patients with ruptured aneurysms have an aorta that is anatomically suitable for endovascular repair.\(^\text{50,55}\)

The method of repair is clearly the surgeon’s decision. Planning for the care of such patients should include development of a well-understood protocol that advises the ED staff about which services to mobilize and which diagnostic tests to obtain when patients with ruptured AAA present.\(^\text{50,56}\)

Diagnostic Confirmation

In the patient with acute abdominal or back pain but without hypotension, more time can be taken to confirm the presence of an AAA. If an AAA can be diagnosed with bedside testing (abdominal examination or ultrasonography), the surgeon often proceeds immediately to the operating room with a clinical diagnosis of aneurysm rupture, because a delay in surgery places the patient with a ruptured AAA at risk for sudden and unpredictable hemodynamic deterioration. If the patient remains hemodynamically stable and an AAA cannot be identified with bedside testing, or if endovascular repair is being considered, abdominal CT can be obtained to confirm or exclude the presence of an aneurysm and define the aortic anatomy and the patient’s suitability for endovascular repair. The patient who is sent for CT must be monitored closely and taken to the operating room immediately if hemodynamic deterioration occurs.

CT can also identify the retroperitoneal hemorrhage associated with rupture and confirm the need for an emergency procedure. The surgeon may want confirmation of rupture to avoid the problems of performing emergency surgery with an intact aneurysm. With emergency surgery, detailed anatomic evaluation and careful preoperative planning are often impossible, evaluation and optimization of the patient’s cardiopulmonary and renal function may be precluded, and invasive hemodynamic monitoring may be unavailable. For these reasons, patients who are taken for emergency surgery and found to have intact, symptomatic aneurysms have a significantly higher mortality rate (20–25%) than patients undergoing elective aneurysm repair (approximately 5%).\(^\text{9,17,28,57}\)

Once an AAA has been diagnosed, the decision to obtain CT to distinguish a ruptured from an unruptured aneurysm should be made very cautiously and in close consultation with a surgeon. If CT demonstrates an intact AAA and the decision is made to delay surgery, the patient must be closely observed
for signs of rupture in an intensive care setting, and a clear alternative explanation for the patient’s presentation (e.g., hypotension, syncope) must be established.

Patients may be hypertensive on admission because of pain or underlying chronic hypertension. Unlike the situation with aortic dissection, no evidence exists that lowering the blood pressure is beneficial in the patient with a ruptured AAA, and these patients are at risk of developing precipitous hypotension.

Surgery and Mortality

Ruptured AAA is uniformly fatal unless treated surgically. Thus, once this diagnosis is made, repair should be attempted in almost all patients. Attempts have been made to identify patients with a very low likelihood of survival, and it has been suggested that surgery can be withheld in patients with out-of-hospital or ED cardiac arrest. However, no variables (including cardiac arrest) that can be assessed in the ED are universally predictive of a fatal outcome. Repair is indicated unless the patient’s life expectancy is very short because of underlying illnesses or the patient’s quality of life is so poor that repair is considered unreasonable.

Surgical mortality in patients with ruptured AAAs is approximately 50% and has shown little improvement in the past three decades. Hypotension is the most important factor predicting a poor outcome.

Operative mortality rates significantly underestimate the true lethality of the ruptured AAA. The patient with a ruptured AAA may die at home or may reach the hospital but die before surgery. When patients who do not reach the operating room are considered, the overall mortality rate is 80 to 90%.

Intact, Asymptomatic Aneurysms

An incidental diagnosis of AAA may be made in the ED. The decision to repair an asymptomatic aneurysm depends on the risk of aneurysm rupture, the patient’s life expectancy and likelihood of dying from other causes, and the surgical risk. The latter factors are determined by the patient’s age and coexisting illnesses. The risk of rupture is largely a function of aneurysm size.

In two recent clinical trials, patients with small (<5.5 cm) aneurysms were randomized to early surgery or close follow-up with serial ultrasonography or CT, and surgery was performed only if symptoms developed, rapid expansion was documented, or a diameter of 5.5 cm was reached. Both studies showed equivalent survival rates in the two groups. As a result, fewer small aneurysms are now repaired electively, potentially leaving a larger group of patients who may present to the ED with complications of an AAA. It is important to note that the “watchful waiting” approach is appropriate only for asymptomatic aneurysms, and rupture of the AAA must be strongly considered when evaluating any symptoms in these patients.

Traditional Repair

The conventional technique for repair of AAAs is an open approach with a laparotomy. The aneurysm is opened longitudinally and repaired from within (Fig. 84-5). A graft is inserted inside the aneurysm and anastomosed to uninvolved vessels above and below. When possible, a straight graft is used between the infrarenal and distal aorta. If the aneurysm involves the aortic bifurcation, or if iliac artery aneurysmal or occlusive disease is present, a bifurcation graft is used, with the distal anastomosis to the iliac or femoral arteries. The aneurysm wall is then closed around the graft to help separate it from adjacent structures.

Endovascular Repair

Many AAAs are now being repaired using endovascular techniques. A stent graft (a fabric graft supported by an internal wire frame) is placed into the femoral artery percutaneously or through a groin incision and is advanced under fluoroscopic guidance to a position that spans the aneurysm (Fig. 84-6A). The contralateral iliac limb is placed to form a bifurcated graft (Fig. 84-6B). Once in position, the graft is expanded to fit tightly against the walls of the aorta. The stent graft may use hooks or barbs to secure it in place. Straight (tube) grafts, used earlier in the development of endovascular repair, are now rarely used because of their high failure rate.

Endovascular surgery avoids the morbidity associated with a laparotomy and allows the repair of AAAs in some high risk patients who would not tolerate conventional surgery. Periop-

![Figure 84-5](https://example.com/84-5.png)

**Figure 84-5.** Steps in repair of an abdominal aortic aneurysm. (1, Incision sites; 2, proximal anastomosis; 3, completed anastomoses; and 4, closure of aneurysm around graft.) (From Kent KC, et al: Surgical principles for operative treatment of aortic aneurysms. In Lindsay J Jr [ed]: Diseases of the Aorta. Philadelphia, Lea & Febiger, 1994, p 287.)

![Figure 84-6](https://example.com/84-6.png)

operative mortality is lower than that with open surgery, although a long-term survival advantage has not been demonstrated.

Not all aneurysms are anatomically suitable for endovascular repair. Detailed preoperative imaging and planning are often required to make this determination. This technique has only recently been applied to patients with ruptured aneurysms. In addition, patients who have had endovascular aneurysm repair remain at risk for several specific complications, including rupture of the aneurysm.

Survival
The mortality rate of elective AAA repair is approximately 5%, in stark contrast to the 50% operative mortality associated with ruptured aneurysms. Patients who survive the operation have an excellent prognosis, with a long-term survival close to that of the general population. After repair of the aneurysm, long-term survival is primarily limited by associated cardiac disease.

Late Complications of Repair
Graft infection, AEF formation, and anastomotic aneurysm (pseudoaneurysm) formation can occur at any time from weeks to many years after the surgery. These complications often occur together, their clinical presentations overlap, and they are diagnosed by similar means. Endovascular aneurysm repair has several unique complications, the most important being endoleak.

Graft Infection
Graft infection can result from contamination of the graft at surgery, spread of a contiguous infection, or hematogenous seeding. Infection can disrupt the anastomosis between native artery and graft, leading to leakage of blood and pseudoaneurysm formation. The infection can be localized to a portion of the graft, most often the inguinal portion of an aortofemoral graft, or can involve the entire graft. Infection of the distal limb of an aortofemoral graft may be clinically evident, with local signs of infection or a palpable false aneurysm. Intra-abdominal graft infection is often subtle, with low-grade fever and vague abdominal or back pain. Abdominal tenderness or a palpable mass may be present at the leaking anastomosis. CT should be performed to evaluate for possible graft infection. Collections of fluid or gas around the graft provide evidence of infection, although CT scans are sometimes falsely negative.

Aortoenteric Fistula
Graft infection may lead to secondary AEF formation. These fistulas, which are much more common than primary AEFs, can develop years after AAA repair or after aortoiliac or aortofemoral bypass surgery for peripheral vascular disease. Secondary AEFs usually form between the proximal aortic anastomosis and the distal duodenum. However, they can occur anywhere in the gastrointestinal tract and cause upper or lower gastrointestinal bleeding.

The clinical presentation of the patient with a secondary AEF may be identical to that of a patient with graft infection alone, with fever and other signs of infection. More often, however, the patient with an AEF has gastrointestinal bleeding. The bleeding can be acute or chronic, and ranges from minor to massive.

An AEF must be considered in any patient with gastrointestinal bleeding and a history of abdominal aortic surgery. Most of these patients, however, ultimately prove to have other, more common causes of gastrointestinal bleeding. The diagnostic approach depends on the patient’s hemodynamic stability.

Diagnostic testing may be dangerously time-consuming if the patient with a possible AEF is unstable with massive bleeding. Emergency laparotomy may be necessary to control hemorrhage and diagnose or exclude the presence of an AEF.

Upper gastrointestinal endoscopy is sometimes recommended as the initial diagnostic test. Direct visualization of the fistula into the distal duodenum is sometimes possible. However, endoscopy cannot be relied on to identify an AEF, and its main value is in establishing another diagnosis. If an active bleeding site other than an AEF is clearly seen, emergency surgery can be avoided.

An abdominal CT scan can also be used to evaluate a suggested AEF. Although imaging of the fistula may not be possible, graft infection is almost invariably present in patients with secondary AEFs, and CT can demonstrate the associated infection. Radiographically distinguishing an AEF from intra-abdominal graft infection alone may be difficult, but the distinction is not crucial because both need surgical management.

Pseudoaneurysm (Anastomotic Aneurysm)
Pseudoaneurysms can arise at the site of a leaking anastomosis. They may be associated with graft infection or AEF formation but more often result from degeneration of the native vessel. The patient with an anastomotic aneurysm may have pain or a pulsatile mass in the abdomen or groin. The aneurysm may give rise to distal emboli or may rupture and cause life-threatening hemorrhage. Suspected pseudoaneurysms can be evaluated with angiography, CT, or ultrasonography.

Complications of Endovascular Aneurysm Repair
The most serious of these complications is endoleak—blood flow outside of the graft lumen but within the aneurysm sac that potentially allows enlargement of the aneurysm. Endoleaks may be caused by separation of the proximal or distal end of the graft from the aortic wall, back-bleeding into the aneurysm sac from branch vessels such as lumbar arteries, leakage between the modular components of the graft, or leakage through the graft fabric itself (Fig. 84-7). Importantly, the patient with persistent leakage of blood into the aneurysm sac is at risk for rupture of the aneurysm.

Endoleaks may develop shortly after the procedure or much later. They have been reported in as many as 20% of patients who have had endovascular aneurysm repair; this percentage is expected to decrease with improvements in device design and insertion techniques. Because many endoleaks resolve spontaneously, patients are sometimes observed for months before repair of the leak.

Patients sometimes sustain other complications such as graft migration, stenosis or thrombosis, and structural failure of various elements of the graft. These complications often lead to endoleak and the risk of rupture.

CT is used to investigate possible complications of endovascular repair. A specific imaging protocol may be desired; this should be discussed with the radiologist or vascular surgeon.
Because of the many potential complications of endovascular aneurysm repair, these patients require close lifelong follow-up. Prompt surgical consultation should be obtained when patients present with any symptoms possibly caused by device malfunction.

**DISPOSITION**

A patient with an acutely symptomatic AAA requires hospital admission and urgent or emergency repair. A patient whose aneurysm is asymptomatic and discovered incidentally should be referred for consideration of elective repair. The patient with an AAA should be referred for an outpatient workup only if it is clear that the symptoms prompting the ED visit are unrelated to the aneurysm. If the patient is discharged, instructions should be given to seek medical attention immediately if abdominal, back, or flank pain develops.

In the patient who has had an AAA repaired, unexplained fever, abdominal pain, or gastrointestinal bleeding suggests the presence of a graft-related complication and the need for inpatient evaluation.
A ruptured AAA should be considered in any patient older than 50 years who presents with abdominal or back pain. The complete triad of pain, hypotension, and a pulsatile mass is often not present.

- In the patient with an AAA and acute symptoms, rupture is imminent or has already occurred.
- The patient with a ruptured AAA who appears to be hemodynamically stable can suddenly deteriorate at any time.

The patient with a ruptured AAA should be moved expeditiously to the operating room and should receive only that testing essential to establishing the diagnosis.

- Resuscitation in the ED should not target normal blood pressure. A systolic blood pressure of 80 to 100 mm Hg is usually sufficient to perfuse the heart and brain.
- The patient who has had endovascular repair of an AAA remains at risk for aneurysm rupture.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
Treatments for peripheral arterial disease date from the late 18th century. In 1785, Hunter demonstrated complete thrombosis of an aneurysmal sac with a ligature proximal to a popliteal aneurysm. In 1877, Eck reported the first successful anastomosis between two vessels, the portal vein and the inferior vena cava. In 1963, surgical embolectomy became widely established with the introduction of the Fogarty balloon catheter. Recent advances in noninvasive hemodynamic testing, imaging techniques, interventional devices, and chronic indwelling catheters present a wide range of new diagnostic and therapeutic challenges.

Arteries are classified into three categories on the basis of their size and histologic features: (1) large or elastic arteries (the aorta and its immediate proximal, larger branches, including the innominate, subclavian, common carotid, and pulmonary arteries); (2) medium-sized or muscular arteries (located just distal to elastic arteries, including the common femoral, axillary, and carotid arteries); and (3) small arteries (usually <2 mm in diameter) that course in the substance of tissues and organs. This chapter considers diseases of medium and small arteries.

Arterial Anatomy

All arteries possess three layers: the tunica intima, tunica media, and tunica adventitia. As peripheral arteries diminish in caliber, these three layers become progressively indistinct and are no longer identifiable at the level of the arteriole (pre-capillary vessel containing smooth muscle).

The tunica intima has an inner lining of endothelial cells surrounded by subendothelial connective tissue. The outer limit of the tunica intima is demarcated by a longitudinally dispersed layer of elastic fibers known as the intimal elastic lamina. The single layer of continuous endothelium is a unique thromboresistant layer between blood and the potentially thrombogenic subendothelial tissues. The integrity of the endothelium is a fundamental requirement for maintenance of normal structure and function of the entire vessel wall. Endothelial injury can result in intraluminal thrombosis and may contribute to the initiation of atherosclerosis.

The tunica media is made up primarily of circular or spiral smooth muscle cells arranged in concentric layers. The outer limit of this layer is marked by a well-defined, external elastic membrane. The elastic content of the tunica media gives resilience to medium-sized arteries. As part of the normal aging process, the elastic fibers deteriorate and are replaced by fibrous tissue. This loss of elasticity results in stretching and elongation and accounts for the progressive tortuosity and development of arterial aneurysms with aging. Vascular smooth muscle cells may be important in lipid accumulation in the vessel wall during atherosclerosis and participate in vasoconstriction and dilatation.

The tunica adventitia is a poorly defined layer of connective tissue in which nerve fibers and small, thin-walled nutrient vessels (vasa vasorum) are dispersed. Medium-sized arteries contain more nerve fibers than larger vessels, reflecting the importance of their role in the autonomic regulation of blood flow.

The peripheral arterial vascular system can be considered as a single end-organ subject to a variety of pathologic conditions. This chapter describes eight basic pathophysiologic processes: (1) atherosclerosis, (2) aneurysm, (3) embolism, (4) thrombosis, (5) inflammation, (6) trauma, (7) vasospasm, and (8) arteriovenous fistula. Two of these—atherosclerosis and thrombosis—are responsible for most peripheral arterial problems.

Pathophysiology

Atherosclerosis is a disease of large- and medium-sized muscular arteries. The basic lesion, the atheroma, or fibrofatty plaque, is a raised focal plaque within the intima; it has a lipid core (mainly cholesterol, usually complexed to proteins and cholesterol esters) covered by a fibrous cap. As the plaques increase in size and number, they progressively encroach on the lumen of the artery and the adjacent media. Atheromas have two main effects: they compromise arterial blood flow and weaken the walls of the affected arteries.

The distribution of atherosclerotic plaques is rather constant. The abdominal aorta has more atherosclerotic disease than the thoracic aorta, and aortic lesions tend to be much more common and prominent around the ostia of major branches. Other vessels greatly affected by atherosclerosis are the aortoiliac, femoral, and popliteal arteries; the descending thoracic aorta; the coronary arteries; the internal carotid arteries; and the circle of Willis. Vessels of the upper extremities are usually spared.
As atherosclerosis progresses, atheromas almost always undergo calcification, resulting in hard, brittle vessels. Ulceration of the luminal surface and rupture of the atheromatous plaques may result in discharge of the debris into the bloodstream, producing atheroemboli (cholesterol emboli). Fissured or ulcerated lesions can produce in situ thrombosis, causing acute intraluminal occlusion.

Hemorrhage into the plaque may further compromise the arterial lumen. Although atherosclerosis primarily affects the intima, in severe cases, the tunica media undergoes pressure atrophy and loss of elastic tissue, with sufficient weakening to create aneurysmal dilatation.

Aneurysms

A true aneurysm is an abnormal localized dilatation of the intact vessel wall. In a pseudoaneurysm, the entire wall perforates or ruptures, and the extravasated blood is contained by the surrounding tissues, eventually forming a fibrous sac that communicates with the artery.

Mural and mechanical factors contribute to true aneurysm formation. The major cause of aneurysms is a weakness or defect in the integrity of the arterial wall. The only aneurysms that develop in a normal arterial segment are poststenotic aneurysms, such as with coarctation. Acceleration of flow past a narrow point creates slower flow beyond the stenosis lateral to the jet stream, producing increased lateral pressure. Aneurysmal dilatation accelerates, increasing the risk of rupture as diameter increases, as predicted by Laplace’s law: tension (lateral pressure) in the wall of a hollow viscus varies directly with its radius (tension = pressure × radius).

The most common cause of aneurysms is severe atherosclerosis resulting from thinning and destruction of the tunica media. Atheromatous ulcers covered by mural thrombi are common within an aneurysm. Such mural thrombi can form emboli that lodge in distal vessels. When an entire aneurysm is filled with thrombus material, arterial occlusion results.

Aneurysms cause clinical symptoms through (1) rupture with subsequent hemorrhage, (2) impingement on adjacent structures, (3) occlusion of a vessel by either direct pressure or mural thrombus formation, (4) embolism from mural thrombus, and (5) presentation as a pulsatile mass.

Arterial Embolism

An embolus is a blood clot or other foreign body that is carried by the blood to a site distant from its point of origin. Most emboli are the result of detached thrombus formation (thromboembolism). Less common sources include debris from ruptured atherosclerotic plaques, tumor debris, or foreign bodies. Unless otherwise specified, the term embolus in this chapter is defined as thromboembolus.

Thromboembolism. Most arterial emboli (85%) originate in thrombus formation in the heart. Left ventricular thrombus formation resulting from myocardial infarction accounts for 60 to 70% of arterial emboli. Atrial thrombi associated with mitral stenosis and rheumatic heart disease account for only 5 to 10% of arterial emboli. Coexisting atrial fibrillation, often without mitral stenosis, is present in 60 to 75% of patients with peripheral arterial embolic events, since atrial fibrillation itself can predispose patients to intracardiac clotting.

Acute arterial emboli often cause distal tissue infarction. Clinical outcome depends mostly on the amount of collateral circulation present but also on the size of the vessel and the degree of obstruction. Patients with long-standing atherosclerosis have well-developed collateral circulation, whereas sudden occlusion of a normal artery without collateral pathways results in severe ischemia. After acute obstruction, the embolus can propagate proximally or distally, fragment and embolize further to distal vessels, or precipitate associated venous thrombosis by initiating a localized inflammatory reaction.

Because vessel diameters change most abruptly at branch points, embolic occlusion most often occurs at major arterial bifurcations. The bifurcation of the common femoral artery is the most frequent site of arterial embolism, accounting for 35 to 50% of all cases. The smaller femoral and popliteal arteries are involved twice as often as the larger aortic and iliac vessels, reflecting the small size of most emboli.

Cell death from arterial ischemia can produce high concentrations of potassium, lactic acid, and myoglobin in the extremity distal to an arterial occlusion. Their sudden release after revascularization can produce life-threatening hyperkalemia, metabolic acidosis, and myoglobinuria. This myonephropathic-metabolic syndrome accounts for approximately one third of the deaths from arterial embolism after revascularization.

Atheroembolism. Atheroembolism refers to microemboli consisting of cholesterol, calcium, and platelet aggregates dislodged from proximal complicated atherosclerotic plaques that lodge in distal end arteries. In the central nervous system, atheroemboli cause transient ischemic attacks and strokes (cerebrovascular accidents). In the peripheral vascular system, atheroemboli characteristically present with cool, painful, and cyanotic toes, or the “blue toe” syndrome (see Fig. 85-2).

Atheroemboli are caused by a proximally located arterial lesion, usually atherosclerotic plaques or aneurysms. Bilateral distal extremity involvement usually implies an aortic source, whereas unilateral atheroemboli usually arise from sites distal to the aorta. Distal lesions are most common in the femoropopliteal arteries (60%) and the aortoiliac arteries (40%). Aortic lesions (e.g., aneurysms, polytetrafluoroethylene grafts) are a less common source of microemboli.

Atheroemboli tend to lodge in arteries, such as the digital arteries, which are 100 to 200 µm in size. Single atheroembolic events seldom result in tissue loss, but atheroemboli tend to cluster. If unrecognized, repeated events ultimately result in loss of collateral circulation, progressive symptoms, and extensive tissue infarction.

Infectious emboli from bacterial endocarditis can produce septic infarcts that may convert to large abscesses. Rarely, cardiac and noncardiac tumors or foreign bodies may gain access to the arterial circulation and embolize. Primary or metastatic lung neoplasms, malignant melanoma, and bullet emboli have been reported. In patients with cyanotic congenital heart disease (e.g., patent foramen ovale), venous embolism may pass directly to the arterial circulation (“paradoxical” emboli). Although rare, this possibility should be considered in any patient with simultaneous arterial and venous emboli, particularly if a source of the arterial embolus is not evident.

Arterial Thrombosis

Thrombosis is the in situ formation of a blood clot within the noninterrupted arterial vascular system. Complicated atherosclerotic plaques are usually responsible for the two major factors that cause in situ thrombosis: endothelial injury and alterations in normal blood flow. Less common causes include acute vasculitis and trauma. Thrombosis is rare in normal arteries.

Peripheral arterial thrombi are usually occlusive, although they may be limited to one wall (mural) in larger vessels. Peripheral arterial thrombi are usually firmly attached to the damaged arterial wall and infrequently embolize. The clot
may propagate proximally and distally, which intensifies the ischemia.

Inflammation

Inflammatory arterial injury can be caused by drugs, irradiation, mechanical trauma, or bacterial invasion. The major cause of arteritis is noninfectious systemic necrotizing vasculitis (see Chapter 116). Most cases of infectious arteritis are caused by direct invasion of the arterial wall. Septicemia, intravenous (IV) drug abuse, or infective endocarditis is most often responsible. Certain fungal infections, particularly aspergillosis and mucormycosis, are frequently associated with vasculitis and thrombosis.

Trauma

Different types of vascular injury result in characteristic pathologic syndromes. Partial arterial lacerations continue to bleed because the intact portion of the vessel wall prevents retraction and closure of the arterial wound. This may form an expanding hematoma, causing progressive deformity, pain, and nerve compression. Complete arterial transection usually has only moderate or insignificant bleeding because of arterial spasm of the transected ends of the artery and the formation of a temporary thrombus. Delayed hemorrhage in completely transected arteries may result from relaxation of arterial spasm, eventual liquefication of the thrombus, or displacement of the thrombus by arterial pressure. Blunt injury may produce partial or complete intimal disruption. Dissection of the distal intima can lead to progressive obstruction and thrombosis. Complete occlusion may not occur for hours or days after injury. Vasoconstriction can accompany injuries that are adjacent to blood vessels; spontaneous resolution always occurs in the absence of arterial disruption or intimal injury.

Vasospasm

Vasospastic disorders (Raynaud’s disease, Raynaud’s phenomenon, livedo reticularis, acrocyanosis, erythromelalgia) produce an abnormal vasomotor response in distal small arteries. The exact cause of these disorders is unknown but is thought to be related to the autonomic innervation of the peripheral arterioles. The vasospastic disorders are characterized by the presence of ischemic symptoms and the absence of tissue loss. True organic changes within the arterial wall are absent. In contrast, patients with digital ulceration and gangrene always have fixed arterial occlusions in the distal extremity arteries.

Arteriovenous Fistulas

Abnormal communication between arteries and veins may result from congenital defects, rupture of an arterial aneurysm into an adjacent vein, penetrating injuries, and inflammatory necrosis associated with neoplasms or infection. Arteriovenous fistulas can occur in any region of the body. The artery proximal to the fistula becomes distended, tortuous, and aneurysmal. Similar changes occur in the venous side of the fistula. Proximal and distal veins respond to alterations in hemodynamics with intimal proliferation and fibrosis, followed by a decrease in the internal elastic lamina, resulting in distention, tortuosity, and aneurysm formation. The resultant chronic venous hypertension may cause dermatitis and ulceration of overlying skin. The size of the opening between artery and vein generally increases with time.

Approximately 60% of arteriovenous fistulas are associated with a false aneurysm. False aneurysm formation can occur as part of the fistulous tract or as the result of arterial or venous dilatation. The increase in cardiac output that occurs when blood switches from the arterial to the venous system can result in a widened pulse pressure or high-output cardiac failure.

■ CLINICAL FEATURES

History

Patients with peripheral arterial disease have pain, tissue loss (ulceration or gangrene), or a change in sensation or appearance (swelling, discoloration, or temperature change). Because the primary cause of peripheral arterial disease is atherosclerosis, related conditions providing evidence of atherosclerosis are cardiac disease, myocardial infarction, cardiac dysrhythmias (e.g., atrial fibrillation), stroke, transient ischemic attacks, and renal disease. Factors that increase the likelihood of atherosclerosis are cigarette smoking, diabetes, hypercholesterolemia, and hypertension. IV drug use can lead to arterial injury. Aortoiliac obstruction can cause sexual impotence in men (Leriche’s syndrome).

Risk factors not related to atherosclerosis include prior injuries or surgeries, major illnesses, a history of phlebitis or pulmonary embolism, the presence of autoimmune disease or arthritis, and a history of prior coagulation abnormalities.

Acute Arterial Occlusion

The patient with acute arterial occlusion usually exhibits some variant of the “five P’s”: pain, pallor, pulselessness, paresthesias, and paralysis. Paresthesias and paralysis indicate limb-threatening ischemia that requires emergency surgical intervention regardless of the cause. In patients with non-limb-threatening ischemia, accurate differentiation between embolism and in situ thrombosis as the cause of acute arterial occlusion determines management. Arterial embolism is best managed by emergency Fogarty catheter embolectomy. Non-limb-threatening ischemia from in situ thrombosis is often aggravated by emergency surgical intervention and is therefore initially best managed nonoperatively, if possible (Fig. 85-1). Acute arterial embolism usually occurs in patients without significant peripheral atherosclerosis and without well-developed collateral circulation. For this reason, acute embolism usually presents as sudden limb-threatening ischemia. Patients describe a sensation of the leg’s being “struck” by a severe shocking pain. Often the patient has to sit or fall to the ground during the event.

In situ thrombosis usually occurs in patients who have long-standing significant peripheral atherosclerosis and well-developed collateral circulation. For this reason, in situ thrombosis often is seen subacutely with non-limb-threatening ischemia. A history of claudication is common with in situ thrombosis and rare in patients with arterial embolism.

Chronic Arterial Insufficiency

Chronic arterial insufficiency causes two characteristic types of pain: intermittent claudication and ischemic pain at rest. The level of arterial occlusion and the location of intermittent claudication are closely correlated. Calf claudication is associated with femoral and popliteal disease. Patients complain of a cramping pain, reliably reproduced by the same degree of exercise and completely relieved by rest (usually 1–5 minutes). Aortoiliac occlusive disease typically causes claudication in the buttocks and hips, as well as the calves. The calf pain in aortoiliac disease is generally more severe than the buttoc...
and thigh pain, which is more often described as an aching, discomfort, or weakness. Some patients even deny pain, complaining only that the thigh or hip “gives out” with exercise. Aortoiliac occlusive disease severe enough to produce bilateral claudication is almost always associated with impotence in men (Leriche’s syndrome). Even in the absence of impotency, bilateral hip or thigh pain in a man should indicate the possibility of aortoiliac occlusive disease.

Chronic arterial insufficiency may progress so that ischemic pain occurs at rest. Rest pain often begins in the feet and typically involves the foot distal to the metatarsals, awakening the patient from sleep. Ischemic rest pain is a severe, unrelenting pain aggravated by elevation and unrelieved by analgesics. Patients often sleep with the leg dangling over the side of the bed or sleep in a chair to improve perfusion pressure to the distal tissues. Patients have prompt relief of pain by any activity that involves a standing position.

**Physical Examination**

A systematic assessment of the peripheral vascular system includes palpation of the pulse volume in the pairs of brachial, radial, femoral, posterior tibial, and dorsalis pedis arteries documented on a scale of 0 to 4+. Carotid arteries should be gently palpated singly and findings similarly documented.

Approximately 10% of the population does not have one of the dorsalis pedis pulses. The lower extremities should be gently palpated singly and findings similarly documented.

Doppler ultrasonography should be used in the emergency department in all patients with questionable or absent pulses. Doppler testing is more sensitive than palpation in detecting peripheral pulses. An estimate of blood flow to the lower extremities can be made by measuring the systolic blood pressure at the level of the ankle and comparing it with the brachial systolic pressure. With the patient supine, a blood pressure cuff is applied just proximal to the malleolus, inflated above brachial systolic pressure, and then deflated slowly. Ankle systolic pressure can be accurately measured with a Doppler probe placed over the dorsalis pedis or posterior tibial artery. This pressure is normally 90% or more of the brachial systolic pressure; with mild arterial insufficiency, it is between 70 and 90%; with moderate insufficiency, between 50 and 70%; and with severe insufficiency, less than 50%.

The Allen test is helpful in assessing patency of the radial or ulnar artery distal to the wrist. The patient initially opens and closes the hand and then clenches the fist to expel as much
blood from the hand as possible; the examiner then compresses the radial and ulnar arteries. When the patient opens the fist, the hand is pale. The examiner then releases pressure from the radial artery but maintains it on the ulnar artery. If the radial artery distal to the wrist is patent, the hand becomes pink rapidly; if it is occluded, the hand remains pale. The maneuver is then repeated by maintaining pressure on the radial artery while releasing the ulnar artery. A comparison can be made with the opposite hand.

**Arterial Embolism**

The physical examination can assist in differentiating between arterial embolism and in situ thrombosis in patients who have acute arterial occlusion. The sudden loss of a previously present pulse is the hallmark of arterial embolism. It is difficult to recognize this finding, however, if the prior pulse status of the limb is unknown or is abnormal as the result of associated atherosclerosis. A bounding pulse may be felt initially at the location of an embolus as a result of transmitted pulsations through the fresh clot. In general, patients with arterial embolism have few physical findings suggestive of long-standing peripheral vascular disease with normal, proximal, and contralateral limb pulses. Occasional tenderness to palpation can be noted at the site of an embolic occlusion.

If arterial embolism is suspected, the physical examination should be directed to identifying its source. The two most common sites are a left ventricular mural thrombus secondary to a prior myocardial infarction and a left atrial thrombus in a patient with mitral valve disease. Coexistent atrial fibrillation is common.

The limb distal to an embolic occlusion is initially chalk white. Because of absence of blood from the venules of the subcapillary layer, the demarcation between ischemic and nonischemic tissue is sharp. With time, cyanosis may appear, indicating desaturation of blood with continued ongoing ischemia. Paresthesia or paralysis indicates limb-threatening ischemia. The presence of sensitivity to light touch is often the best guide to viability of the tissue. Complete anesthesia demands immediate surgical intervention. Paralysis represents severe skeletal muscle and neural ischemia, which may be irreversible. Involuntary muscle contracture with woody hardness represents irreversible ischemia.

**Arterial Thrombosis**

Physical findings of in situ thrombosis are often accompanied by evidence of atherosclerotic occlusive disease. Proximal or contralateral limb pulses are usually diminished or absent. An identifiable source of an embolus, such as mitral valve disease or atrial fibrillation, is usually not present. Because of collateral circulation, demarcation of limb ischemia is less well defined in these patients (Table 85-1).

Carotid, renal, and femoral arteries may have bruises, and there may be evidence of abdominal aortic aneurysm. If an occlusion of the upper extremity vessels is suggested, the subclavian artery should be evaluated by palpating for thrills and listening for bruits in the supraclavicular fossa.

A funduscopic examination allows direct visualization of retinal arterioles that may yield evidence of arteriosclerosis or hypertension. Hollenhorst plaques (atheromatous emboli containing cholesterol crystals in the retinal arterioles) may be detected. Roth’s spots (round or oval white spots seen near the optic disk) may be present in patients with infective endocarditis.

Emolic phenomena can cause diverse end-organ damage: hemiplegia from cerebral emboli, flank pain with hematuria from renal emboli, left upper quadrant abdominal pain from splenic infarcts, and pleuritic pain with hemothysis from pulmonary emboli. Septic pulmonary embolism from right-sided endocarditis may be confused with pneumonia.

**Inflammation**

Inflammatory vascular disease manifests primarily as skin involvement. Skin lesions typically appear as palpable purpura; other cutaneous manifestations of vasculitis include macules, papules, vesicles, bullae, subcutaneous nodules, ulcers, and recurrent or chronic urticaria. The skin lesions may be pruritic or even painful, with a burning or stinging sensation. Lesions more often occur in dependent areas: in the lower extremities in ambulatory patients or in the sacral area in bedridden patients. Edema accompanies some lesions, and hyperpigmentation often occurs in the areas of recurrent or chronic lesions.

**Vasospasm**

Vasospastic disorders cause a sharp border between ischemic and normal tissue. Raynaud’s disease is characterized by intermittent attacks of triphasic color changes: pallor, cyanosis, and then rubor. The most important element is pallor, during which the digits turn chalk white. Attacks generally last 15 to 60 minutes, and rewarming the hands restores normal color and sensation. Color changes do not occur above the metacarpophalangeal joints and rarely involve the thumb.

Two other vasospastic disorders have a characteristic appearance. Livedo reticularis is characterized by a persistent cyanotic mottling of the skin that has a typical “fishnet” appearance and may involve all parts of the extremities and trunk. Acrocyanosis is the least common vasospastic disorder and is characterized by persistent, painless, diffuse cyanosis of the fingers, hands, toes, and feet. Cyanosis usually intensifies with exposure to cold and decreases with warming. The involved parts are nearly always cold, exhibit excessive perspiration, and have normal arterial pulses.

Arteriovenous Fistulas

Arteriovenous malformations and fistulas, although rare, must be distinguished from vascular bruits or aneurysms. True aneurysms and arterial stenoses are associated with a systolic murmur. Pseudoaneurysms generally have a loud systolic and sometimes a separate faint diastolic murmur. Arteriovenous fistulas have a constant systolic and diastolic (to-and-fro) murmur heard best directly over the lesion and often associated with a palpable thrill, precisely analogous to the findings of a therapeutic dialysis arteriovenous fistula. Unless congenital, arteriovenous fistulas occur at prior operative or trauma sites. The skin overlying the lesion may be warm, but distally the temperature is often decreased. Veins peripheral to the fistula are usually distended and varicose. Large and long-standing arteriovenous fistulas produce high cardiac output and widened pulse pressure. Tachycardia in these patients may suddenly decrease when the artery leading to the fistula or the fistula itself is occluded (Branham’s sign).

■ DIAGNOSTIC STRATEGIES

An accurate diagnosis of peripheral arterial occlusive disease can be achieved in most patients by careful history and physical examination supplemented by bedside testing.

Noninvasive Assessment

Doppler ultrasonography measures blood flow velocity by detecting the frequency shift of sound waves reflected from red blood cells that move toward and away from the transducer. The Doppler signal generates a normal triphasic velocity waveform. Progressive arterial narrowing alters the triphasic waveform to biphasic and finally monophasic shape. Such Doppler ultrasonographic waveform analysis can detect significant arterial occlusive disease, although it is less accurate in determining exact location.

Ultrasound uses differences in sound wave reflection from the interfaces between tissues with different acoustic impedances to provide anatomic detail of underlying structures. Ultrasound is useful in detecting and evaluating atherosclerotic plaques and mural thrombi and in sizing aneurysms of the abdominal aorta and iliac, femoral, and popliteal arteries. B-mode ultrasonography is noninvasive, painless, less expensive than other modalities, and universally available. Bedside ultrasonographic studies can lead to rapid diagnosis of life-threatening conditions and reduce the number of delayed or invasive diagnostic procedures. B-mode ultrasonographic imaging is the diagnostic procedure of choice for the initial evaluation and determination of the size of peripheral artery aneurysms.

Duplex scanning combines the image of B-mode ultrasonography and sophisticated online computer analysis of accurately sampled Doppler waveforms to allow simultaneous acquisition of both the image of a vascular structure and the characteristics of blood flow velocity within it. Duplex scanning permits noninvasive and accurate diagnosis of peripheral vascular, cerebrovascular, and venous disease.

Color imaging of blood flow has been combined with duplex scanning and is known as color-coded Doppler, Doppler angiography, or angiodynography. Color flow imaging is achieved by assignment of colors to the direction of blood flow detected by Doppler waveform signals. Red represents flow away from and blue represents flow toward the probe. Color-coded Doppler, the procedure of choice for most conditions, allows noninvasive and accurate detection of atherosclerotic plaques and stenoses, their effect on intraluminal blood flow, and the presence of venous thrombosis.

Invasive Contrast Arteriography

Angiography is the definitive test of abnormal peripheral artery anatomy but is often inconclusive about the physiologic condition of the tissues. Adverse effects of contrast media and catheter-related complications must be weighed against the benefits of this procedure. Contrast media have a direct toxic effect on vascular endothelium; can produce renal failure, especially in diabetic patients; may cause peripheral vasodilation with hypotension; may result in seizures and stroke in neurologic patients; and can cause severe idiosyncratic and allergic reactions. Catheter-related complications, including embolization, catheter breakage, and vascular disruption, vary with operator skill and anatomic location but average 0.5%. The overall mortality rate from angiography is 0.03%. Emergency angiography is usually required in the following circumstances: (1) acute arterial embolus or thrombosis if the clinical diagnosis is uncertain, (2) consideration of emergency vascular bypass grafting, and (3) characterization of vascular abnormality before emergency surgical correction. A decision to proceed with angiography should be made with the vascular surgeon.

Computed Tomography and Magnetic Resonance Imaging

Angiography using spiral computed tomography (CT), called computed tomography angiography, is the most useful diagnostic modality for the evaluation of the abdominal aorta. In the peripheral arteriovascular system, CT angiography is useful primarily for atherosclerotic, infected, and false aneurysms and for imaging the cerebral circulation. Magnetic resonance imaging (MRI) has the capability for angiography (magnetic resonance angiography) that has been particularly useful in delineating cerebrovascular problems (see Chapter 99) and is seeing expanded use in the evaluation of peripheral vascular disease. The ability to make axial, coronal, and sagittal sections provides accurate visualization of anatomy. MRI detects changes in the relaxation variables of tissues before obvious structural changes, uniquely differentiating blood, thrombus, fat, and fibrosis.

■ MANAGEMENT OPTIONS

The management of acute arterial occlusion depends on the degree and cause of ischemia. Patients with limb-threatening ischemia from embolism should have emergency Fogarty catheter embolectomy. Patients with limb-threatening ischemia caused by in situ thrombosis require direct or Fogarty catheter thrombectomy combined with vascular bypass grafting. Thrombectomy alone often fails because of recurrent thrombosis. Patients who have a lesion that cannot be bypassed, who have evidence of irreversible ischemia, or who are too ill to tolerate revascularization are treated with primary amputation.

A patient with non-limb-threatening ischemia from embolism still is treated with Fogarty catheter embolectomy. Non-limb-threatening ischemia from in situ thrombosis is best managed nonoperatively with immediate systemic heparinization and possibly with intra-arterial fibrinolytic therapy (see Fig. 85-1).

Elective surgical repair of an asymptomatic atherosclerotic peripheral arterial aneurysm is usually accomplished by excision of the aneurysm with end-to-end anastomosis or

Fibrinolytic Therapy

Low-dose intra-arterial fibrinolytic therapy is increasingly used for acute arterial occlusion. Patients with limb-threatening ischemia are not candidates because clot lysis generally takes 6 to 72 hours. Patients with an acute arterial embolism cannot tolerate several more hours of ischemia without tissue or limb loss. Fibrinolytic therapy is generally reserved for patients with situ thrombosis and non-limb-threatening ischemia.

Intra-arterial fibrinolytic agents induce clot lysis in the small, distal runoff vessels, decreasing outflow resistance and enabling the native artery to remain open longer. Fibrinolysis often uncovers a critical stenosis that, untreated, may lead to another episode of thrombosis. After successful fibrinolytic therapy, most patients require secondary bypass grafting or percutaneous transluminal angioplasty. Streptokinase, urokinase, and tissue plasminogen activator have all been used successfully. Intravenous administration of a fibrinolytic agent is less effective than direct administration into the clot. Clots more than 30 days old are more organized and less likely to achieve successful lysis.

graft interposition. Infected true and false peripheral aneurysms require aneurysm resection, débridement of infected tissue, and ligation of the proximal and distal uninfected arteries. Autogenous vein bypass through uninfected tissue planes is attempted, but prosthetic grafts carry a high risk for graft infection. The surgical approach to noninfected false aneurysms is similar to that of peripheral atherosclerotic aneurysms.

Patients with thoracic outlet syndrome who have cervical ribs, arterial involvement, or significant neurologic symptoms require surgical decompression with removal of anomalous fibromuscular bands and resection of the first rib, if present. Subclavian and subclavian-axillary aneurysms can be treated with resection and end-to-end anastomosis, graft reconstruction, or surgical revision. Patients with distal embolic occlusions are treated with Fogarty catheter embolectomy. Axillary and subclavian vein thromboses are best managed with surgical thrombectomy or systemic fibrinolytic therapy. Patients with only brachial plexus involvement and minimal signs and symptoms should be followed closely with conservative treatment.

Surgical treatment of peripheral arteriovenous fistulas requires interrupting the fistula tract and restoring both arterial and venous continuity with end-to-end anastomosis or graft interposition. If the anatomic location precludes surgical intervention, percutaneous transvascular embolization with liquid tissue adhesives (e.g., isobutyl 2-cyanoacrylate) is usually successful.

Noninvasive Therapy

Acute Anticoagulation with Heparin

Intravenous heparin is an important emergency department therapy for patients with acute arterial embolism, acute arterial thrombosis, and subclavian vein thrombosis. Heparin should be immediately and empirically started at standard IV doses (80 U/kg by IV bolus, followed by a maintenance infusion of 18 U/kg/hr). Heparin quickly reduces thrombin generation and fibrin formation, minimizing clot propagation, which can intensify limb ischemia and jeopardize tissues. Relative contraindications include recent neurosurgery (especially within 2 weeks), major surgery within 48 hours, childbirth within 24 hours, a known bleeding diathesis, thrombocytopenia, a potentially hemorrhagic lesion, and active bleeding.

Fibrinolytic Therapy

The initial success and long-term patency achieved by angioplasty depend on the location of the lesion and the extent of atheromatous disease. Proximal larger arteries (e.g., iliac, femoropopliteal) have the best initial and long-term results. Discrete stenotic lesions (<5 cm) have better long-term patency rates than those vessels that are diffusely involved or have multiple involved segments. Balloon angioplasty is the accepted treatment for isolated stenotic lesions in the renal, iliac, and superficial femoral vessels.

Transluminal angioplasty with intravascular stent is used in more distal vessels, including the popliteal and tibial circulation, in cases of more diffuse lesions, and for patients who are prohibitive surgical risks, although its value remains to be determined. Recanalization devices include the percutaneous athereectomy catheter, percutaneous angioscope, hot-tip laser, excimer laser, and high-speed rotating wire and drill.

Grafting

Vascular grafting is associated with a variety of complications that can be diagnosed in the emergency department. Autogenous vein grafts (usually a reversed greater saphenous vein) provide excellent long-term patency for small arteries. Vein grafts respond to arterial pressure with gradual intimal proliferation and medial fibrosis. They may develop atherosclerosis, which can lead to graft stenosis and thrombosis. False aneurysms can form along the suture line.

Polytetrafluoroethylene (Teflon) prosthetic grafts are widely used in medium and large arteries that are impossible to bridge with smaller vein grafts. Prosthetic grafts have a higher rate of thrombosis than venous grafts. Distal emboli may result from poor fixation of luminal fibrin. If the prosthetic graft has not been adequately covered by viable tissue, it can erode into adjacent structures and hollow viscera. Prosthetic graft infection is a devastating complication requiring removal of the entire graft.

Vascular grafts can be used to bypass arterial occlusions and reconstruct a diseased arterial bifurcation, or they can be interposed between sections of resected artery. The two most common complications of both prosthetic and vein grafts are thrombosis and development of a false aneurysm at one or more suture lines. Bypass grafting is most often used as palliative treatment for symptoms of atherosclerotic occlusive disease. Patients with localized unilateral stenosis (<3–5 cm in length) may have a comparable rate of success with percutaneous transluminal angioplasty with or without stent placement. Patients with calf claudication from superficial femoral or popliteal occlusive disease can avoid rapid progression of
disease if they stop smoking and maintain an active exercise regimen. Patients who have progression of disease, significant rest pain, or tissue loss require surgical revascularization.

Sympathectomy

Lumbar sympathectomy is no longer used for treatment of ischemia from arterial occlusion. The benefit of sympathectomy in patients with symptomatic Raynaud's phenomenon is unclear, but it remains a potential intervention to assist healing of superficial ischemic ulcers and relieve rest pain in patients with Buerger's disease.18

Hyperbaric Therapy

Scant objective evidence indicates that hyperbaric therapy alters the long-term course of chronic oblitative vascular disorders, presumably by accelerating formation of fine vessels. More success has been achieved with healing chronic diabetic ischemic ulcers and salvaging ischemic skin grafts and flaps.19 Referral to a hyperbaric unit for chronic therapy should be made by the patient's primary physician or vascular surgeon and not in the emergency department.

**SPECIFIC ARTERIOVASCULAR DISEASES**

### DISEASES OF CHRONIC ARTERIAL INSUFFICIENCY

**Arteriosclerosis Obliterans**

Arteriosclerosis obliterans (atherosclerotic occlusive disease, chronic occlusive arterial disease, obliterative arteriosclerosis) is the peripheral arterial presentation of atherosclerosis. Most often, arteriosclerosis obliterans affects the lower abdominal aorta, the iliac arteries, and the arteries supplying the lower extremities. Upper extremity manifestations are rare.

Arteriosclerosis obliterans is responsible for 95% of cases of chronic occlusive arterial disease. It is most common in persons older than 50 years, but as many as 19% of cases occur in patients between the ages of 30 and 49 years. Men are affected more often than women (5:1 to 10:1). Approximately one third of patients with arteriosclerosis obliterans have coexistent coronary artery disease. The incidence of diabetes mellitus is 20 to 30%.20

As with other atherosclerotic diseases, risk factors for arteriosclerosis obliterans include cigarette smoking, hyperlipidemia, and hypertension. Of patients with arteriosclerosis obliterans, 70 to 90% are smokers when first examined, 75% have hyperlipidemia, and 30% have hypertension.20

**Clinical Features and Differential Diagnosis**

Acute arterial occlusion from embolism, thrombosis, or trauma is ruled out primarily by history. Atheromatous emboli from proximal ulcerated plaques or aneurysms can cause small scattered ischemic lesions in the toes, feet, or legs, which may cause blue toe syndrome (Fig. 85-2). The peripheral pulses are present in the blue toe syndrome. Exercise-induced claudication must be distinguished from the nocturnal muscle cramps that frequently occur during rest in elderly patients. Aortoiliac occlusive disease must be differentiated from osteoarthritis of the hip, which tends to be more variable from day to day, is not relieved completely with rest, and is not reliably reproduced by the same amount of exercise. Pseudoclaudication from the cauda equina syndrome is caused by narrowing of the lumbar canal from spondylosis, disease of the intervertebral disks, or spinal cord tumor. Symptoms mimic intermittent claudication but are less closely related to exercise and rest than true claudication.

The cause of lower extremity ulcers should be carefully determined. Approximately 5% of lower extremity ulcerations are caused by arterial insufficiency.21 These are usually located distal to the ankle, typically at the terminal portion of the digits, around the nail beds, or between the toes, caused by friction of one toe on another. Less common locations include the metatarsal heads, heel, and malleoli. Arterial insufficiency ulcers are painful but improve when the extremity is in a dependent position. They are associated with evidence of coexistent chronic arterial insufficiency (absence of hair growth on the dorsum of the feet, skin atrophy, absent pulses, and nail deformities). Ulcers are initially small, shallow, and dry. The base is gray, yellow, or black, with minimal or no granulation tissue. The rim of the ulcer is sharp and indolent, showing no signs of cellular proliferation or epithelialization.

Approximately 90% of lower extremity ulcers are caused by chronic venous insufficiency.23 These typically occur proximal to or in the region of the ankle, especially near the medial malleolus. Venous stasis ulcers are only mildly painful and improve with elevation of the extremity. Evidence of longstanding chronic venous insufficiency, including edema, prominent superficial veins, and stasis dermatitis, is present. Ulcers are moderate in size, with a weeping base and extensive granulation tissue. A rapidly developing ulcer is more suggestive of venous insufficiency.

Most of the remaining lower extremity ulcers are caused by diabetic neuropathy, alone or with arterial insufficiency.23 The location reflects sites of repeated trauma, including the toes, heels, and plantar surface of the feet, especially the metatarsal heads. Neurotrophic ulcers are typically painless. Patients may have evidence of coexistent peripheral arterial insufficiency.
The ulcers are deep and penetrating, often with suppurative drainage caused by an underlying infection or chronic osteomyelitis. Neurotrophic ulcers are usually surrounded by a rim of thick callus.

Hypertensive ulcers are rare and reflect long-standing, uncontrolled hypertension. These ulcers are typically near the lateral malleolus and start as painful, reddish blue areas of infarcted skin. A hemorrhagic bleb develops, then breaks down into a superficial ulcer, which can reach a size of 5 to 10 cm. The ischemic ulcer has sharply demarcated borders, little granulation tissue, and minimal drainage. The pain is the most severe of all lower extremity ulcers.

Multiple ischemic ulcerations above and below the ankle should suggest vasculitis or atheromatous embolization. Ulcers with regular edges in unusual locations may be factitial or may result from subcutaneous injection of illicit drugs. Thickened, rolled, and elevated edges with a central depression containing granulation tissue are characteristic of malignant ulcers.

Management

The first step is to identify patients whose symptoms are the sole result of arteriosclerosis obliterans without coexistent thromboembolic disease. Treatment is dictated by the classification of symptomatic patients into two groups: those with functional ischemia and those with limb-threatening ischemia. Initial assessments and treatments should be made in conjunction with appropriate vascular surgery consultation.

Patients with limb-threatening ischemia constitute a surgical emergency. Angiography should be arranged to identify sufficiently localized disease to permit emergency bypass grafting. Patients with functional ischemia should have outpatient arrangements for noninvasive vascular testing or elective invasive contrast arteriography to determine treatment options such as bypass grafting. Ischemic ulcers or skin lesions should be cultured in the emergency department. Systemic antibiotics to cover skin organisms should be instituted if infection is present. Wet to dry dressings may help debride ulcers containing fibrin, debris, or infection. Radiographs of the underlying bones should rule out osteomyelitis. Patients with ischemic rest pain require hospitalization even if they are not surgical candidates. Bedrest, a warm environment, and maintenance of the limb in a dependent position usually relieve pain.

Buerger’s Disease (Thromboangiitis Obliterans)

First described by Buerger in 1908, thromboangiitis obliterans is an idiopathic inflammatory occlusive disease primarily involving the medium-sized and small arteries of the hands and feet. Patients are usually men between 20 and 40 years of age who use tobacco, although recent reports indicate an increasing frequency of this disease in women. Buerger’s disease affects all races but is more prevalent in the Middle East. The incidence in the United States is 20 in 100,000. The exact pathogenesis of Buerger’s disease is unknown, but virtually all patients are smokers.

Thromboangiitis obliterans is characterized by segmental acute and chronic inflammation in the smaller arteries of both upper and lower extremities. The initial arterial inflammatory process progresses to affect the adjacent veins and nerves, often leading to associated venous thrombosis and progressive fibrous encasement of these structures. This is recognized clinically as painful, tender, reddened, or dark nodules over a peripheral artery with either a reduced or an absent pulse (phlebitis migrans).

Clinical Features

Clinical criteria for the diagnosis of Buerger’s disease include (1) a history of smoking, (2) onset before the age of 50, (3) infrapopliteal arterial occlusive lesions, (4) either upper limb involvement or phlebitis migrans, and (5) absence of athero- sclerotic risk factors other than smoking. A characteristic symptom of Buerger’s disease is foot or instep claudication caused by infrapopliteal arterial occlusion. Intense rubor of the affected extremity, particularly with dependency, is also characteristic. Foot pulses may be absent in the presence of normal femoral and popliteal pulses. Involvement of the hands is often bilateral and symmetrical, leading to the development of hand claudication or fingertip ulcers. Phlebitis migrans occurs early in the disease. Approximately 50% of patients experience Raynaud-type triphasic color response to cold. In the upper extremities, the digital arteries are usually more involved than the radial or ulnar arteries.

Diagnostic Strategies

Adherence to diagnostic clinical criteria should be sufficient for emergency department diagnosis of Buerger’s disease. Noninvasive vascular laboratory testing can confirm the diagnosis and determine the extent of involvement. Although rarely required, angiography demonstrates multiple segmental occlusions.

Differential Diagnosis

Arteriosclerosis obliterans is most likely in patients older than 50 years who have signs of peripheral ischemia. In young women, autoimmune diseases such as scleroderma or systemic lupus erythematosus should be considered.

Management

Permanent complete abstinence from tobacco is the only known effective treatment for Buerger’s disease. If a patient does not completely stop smoking, alternating periods of quiescence are followed by exacerbations of severe arterial insufficiency. Patients who permanently abstain from smoking have a benign clinical course. Despite this, many individuals who have Buerger’s disease continue to smoke even though they experience severe pain at rest, tissue loss, and eventually amputation.

With early symptoms without threat of tissue loss, patient education and follow-up with a vascular surgeon are sufficient. Vascular surgery treatment options are varied for patients with severe symptoms or threatened tissue loss. Intractable pain can be controlled with epidural anesthesia. Intra-arterial or IV prostaglandin E1 and antithrombotic agents, including aspirin and heparin, have been used successfully. Patients with large-vessel arterial occlusion may benefit from arterial reconstruction. Sympathectomy is a potential treatment in advanced cases for cutaneous ulceration or relief of rest pain. Because patients with Buerger’s disease have good healing, intensive conservative treatment is usually successful in avoiding surgical amputation.

DISEASES OF ACUTE ARTERIAL OCCLUSION

Arterial Embolism

Despite advances in diagnosis and treatment, acute arterial embolus continues to be associated with substantial morbidity
and mortality. Approximately 50% of acute arterial occlusions are caused by arterial embolism and the incidence appears to be increasing. The other 50% are caused by in situ thrombosis.3

Differential Diagnosis

Phlegmasia cerulea dolens is a massive iliofemoral deep venous thrombosis. The initial symptom may be acute onset of a swollen and painful leg. As swelling continues, secondary arterial insufficiency with associated pallor (phlegmasia cerulea alba) may occur. In cases of acute arterial embolism, leg swelling is not usually present, especially not at the onset of pain. In addition, acute embolism produces a sharply demarcated pallor; phlegmasia cerulea dolens causes a cyanotic-appearing leg.

Aortic dissection may involve the arteries of the upper or lower extremity and may mimic acute embolus. A history of progressive severe pain, the presence of aortic insufficiency, and involvement at multiple sites suggest dissection. Acute neurologic syndromes (e.g., transverse myelitis, spinal subarachnoid hemorrhage, ruptured intervertebral disk) may produce sudden onset of unilateral or bilateral lower extremity weakness or sensory loss that mimics an acute aortic saddle occlusion.

Cold, blue extremities may result from low-output states such as hypovolemia, decreased cardiac output, dehydration, myocardial infarction, and pulmonary emboli in patients with long-standing atherosclerotic disease.

Management

Acute arterial embolism is a surgical emergency. The likelihood of limb salvage decreases after 4 to 6 hours. On the basis of clinical diagnosis alone, full doses of IV heparin should be administered immediately to minimize clot propagation. Patients whose history and physical examination clearly indicate an acute arterial embolism should undergo immediate Fogarty catheter embolectomy without prior angiography. In these patients, preoperative ultrasonography and angiography are rarely useful diagnostically and prolong the limb’s ischemic status.

If the differentiation of acute embolism and in situ thrombosis is uncertain, pretreatment angiography is required and usually diagnostic. Patients with acute emboli generally show minimal signs of atherosclerosis, occlusion at the site of an arterial bifurcation, sharply demarcated cutoffs, and lack of flow distal to the occlusion. In patients with in situ thrombosis, arteriography shows diffuse atherosclerosis, occlusion at sites other than arterial bifurcations, a tapered irregular cutoff, and well-developed collateral vessels. In general, emboli tend to lodge at arterial bifurcations, whereas arterial thrombi do not (see Table 85-1).

Intra-arterial thrombolytic therapy for acute embolism remains investigational. Immediate limb-threatening ischemia precludes consideration of treatment with thrombolytic therapy in most patients. Potential risks of thrombolytic therapy in arterial embolism patients with non-limb-threatening ischemia include partial clot lysis with further distal embolization or recurrent embolic events from the primary source of the initial embolus.25

Atheroembolism (Blue Toe Syndrome)

Atheroemboli are microemboli consisting of cholesterol, calcium, platelet aggregates, and hemorrhagic debris that break off from proximal atherosclerotic plaques or aneurysms and lodge in distal end arteries. In the central nervous system, atheroembolism causes transient ischemic attacks and strokes. In the peripheral vascular system, atheroemboli characteristically are found in the lower extremities with cool, painful cyanotic toes in the presence of palpable distal pulses (see Fig. 85-2).

Clinical Features

The typical presentation of atheroembolism is the sudden onset of a small painful (cyanotic and tender) area on the foot, typically the toe.26 If bilateral involvement is present, the distribution is not symmetrical. Posterior tibial and dorsalis pedis pulses are present. The physical examination should be directed toward identification of a proximal source, such as an atherosclerotic aneurysm in the aorta or iliac, femoral, or popliteal artery.

Differential Diagnosis

A variety of conditions can mimic the blue toe syndrome. Acrocyanosis is painless, has a symmetrical distribution, and is located in the hands, nose, and lips. Poor peripheral perfusion as a result of low cardiac output must also be considered. Vasculitis, typically, has palpable purpuric lesions and is associated with constitutional symptoms of low-grade fever, myalgias, and weight loss. Previous frostbite may leave the extremities sensitive to cold. Local injury to the foot of the diabetic patient is easily differentiated.

Management

Treatment is directed toward identifying and removing the proximal source of atheroembolism. Angiography is the most accurate diagnostic method for determining the source of emboli. If the source is an aortic aneurysm and the patient is a surgical candidate, operative repair should be performed. Stenotic lesions in the iliac or femoral arteries can be treated with local endarterectomy, vascular bypass, or angioplasty.26 Medical management with aspirin, dipyridamole, crystalline warfarin sodium (Coumadin), or steroids has variable results.

Arterial Thrombosis

Approximately 50% of acute arterial occlusions are caused by in situ thrombosis.2 Acute arterial thrombosis is almost always superimposed on a complicated atherosclerotic lesion but can be caused by vasculitis or trauma. With limb-threatening ischemia, angiography can evaluate the feasibility of emergency bypass grafting. In patients with non-limb-threatening ischemia, angiography may be required if the clinical distinction of acute embolism and thrombosis is difficult (see Table 85-1).

Management

Systemic heparinization should be immediately established in the emergency department. Patients with severe limb-threatening ischemia require emergency direct or Fogarty catheter thrombectomy combined with bypass grafting. Simple thrombectomy alone often fails as a result of rethrombosis. Patients who have atherosclerotic disease not amenable to vascular bypass, who are too ill to tolerate revascularization, or who have irreversible ischemia require primary amputation. Patients with non-limb-threatening ischemia are best treated nonoperatively with heparin and low-dosage intra-arterial thrombolytic therapy.
PERIPHERAL ARTERIAL ANEURYSMS

A true aneurysm is an abnormal localized dilatation of the intact wall of any vessel caused by a combination of mural weakness and hemodynamic forces. Aneurysms enlarge at a rate governed by the cause of the lesion. Those caused by atherosclerosis progress slowly over years; those caused by trauma or infection enlarge over days, weeks, or months. The primary risk of central aneurysms (abdominal aorta, iliac arteries, and visceral arteries) is rupture (see Chapter 84). Peripheral arterial aneurysms rarely rupture; instead, they are complicated by thrombosis or embolism that jeopardizes distal tissues.27

The cause of an aneurysm depends on its anatomic location. Lower extremity aneurysms are most often atherosclerotic in origin. Upper extremity aneurysms are usually caused by localized trauma. Visceral aneurysms result from abnormal hemodynamics, atherosclerosis, or infectious causes.

Lower Extremity

Femoral and popliteal artery aneurysms almost always occur in older men with advanced atherosclerosis. Twenty-five percent of patients have distal atheroembolism or thromboembolism; an additional 15% have total occlusion from in situ thrombosis.27 Popliteal aneurysms are the most common peripheral aneurysms and occur bilaterally in approximately 60% of patients.27 An abdominal aortic aneurysm occurs in almost 80% of patients with bilateral popliteal aneurysms. Most patients have claudication, thromboembolic events, atheroembolic events, or gangrene. Aneurysmal dilation can cause venous compression with associated deep venous thrombosis.

Femoral aneurysms are the second most common peripheral aneurysms and manifest similarly to popliteal aneurysms. Femoral aneurysm dilation can also compress the femoral nerve, producing anterior thigh pain or weakness. Diagnosis of both popliteal and femoral aneurysms is made by palpation of a pulsatile mass. Plain radiographs may show unilateral or bilateral calcified aneurysms. Ultrasonography and CT are diagnostic. Arteriography yields definitive diagnosis and indicates involvement of distal vessels. Patients with a lower extremity aneurysm should be evaluated for the presence of other aneurysms.

Asymptomatic patients can undergo elective surgical excision of the aneurysm and end-to-end anastomosis or graft interposition. Simultaneous repair of coexisting abdominal aorta or contralateral extremity aneurysms combined with vascular bypass is typically done. Patients with limb-threatening thromboembolic events are first treated with Fogarty catheter embolectomy.27

Upper Extremity

Peripheral arterial aneurysms in the upper extremities are rare. Atherosclerosis generally spares the upper extremities, making localized trauma the most common cause.

The causes of proximal subclavian artery aneurysms are thoracic outlet obstruction, trauma, and, rarely, atherosclerosis. Subclavian aneurysms from atherosclerosis represent severe disease, and 30 to 50% of patients so afflicted also have aortoiliac or other peripheral aneurysms.26 Symptoms depend on the aneurysm's anatomic location. Patients may have chest, neck, and shoulder pain from acute expansion. Compression of the right recurrent laryngeal nerve can lead to voice change. Compression of the trachea can lead to stridor or other respiratory complaints. The chest radiograph may reveal a superior mediastinal mass, easily confused with a neoplasm.

The subclavian artery can be compressed by a complete cervical rib that articulates with the first rib, producing a poststenotic dilation in the proximal subclavian and distal axillary artery. This syndrome occurs more often in women and in the dominant upper extremity. Cervical ribs occur in only 0.6% of the population.29 Axillary artery aneurysms are most often caused by blunt trauma from inappropriate and prolonged use of crutches. Humerus fracture and anterior shoulder dislocation are less common causes.28

Subclavian, subclavian-axillary, and axillary artery aneurysms share the common complications of thromboembolism and limb-threatening ischemia, neuromuscular and sensory dysfunction from brachial plexus compression, and central nervous system ischemia produced by retrograde thromboembolism in the vertebral and right carotid circulation. A systolic bruit with a palpable thrill is common.

Arteriography to confirm the diagnosis and determine involvement of distal vessels is the diagnostic procedure of choice. Surgical treatment consists of aneurysm resection, vascular grafting, and reestablishment of arterial continuity.

The rare syndrome of ulnar artery aneurysm (hypothenar hammer syndrome) is associated with occupational trauma in which the heel of the palm is used to hammer, push, or twist objects.30 Patients are often mechanics, carpenters, and machinists.

The ulnar artery fits snugly into the bony canal at the hypothenar eminence under the hook of the hamate bone. Long-term repetitive damage to this region results in aneurysm formation.30 The aneurysm may develop a mural thrombus that repeatedly embolizes to the superficial palmar arch or to a digital artery. Symptoms consist of paresthesias, pain, coolness, and cyanosis; most often in the little and ring fingers and occasionally in the middle and index fingers. The thumb is characteristically spared because of its radial artery blood supply. Diagnosis is easily made by finding a pulsatile or nonpulsatile tenderness in the hypothenar eminence of the dominant hand. The Allen test may demonstrate occlusion of the ulnar artery. Angiography of the distal vessels is diagnostic. Proximal angiography rules out the subclavian and axillary arteries as embolic sources. Treatment requires surgical resection of the aneurysm and reestablishment of ulnar artery continuity. Adjunctive preoperative fibrinolytic therapy may be helpful.30

Viscera

Splenic Artery Aneurysms

Splenic artery aneurysms account for 60% of all visceral arterial aneurysms. They are the only aneurysms that are more common in women, with a female-to-male ratio of 4:1.31 The development of aneurysms in the splenic artery has been attributed to systemic arterial fibrodysplasia, portal hypertension, and increased splenic arteriovenous shunting that occurs in pregnancy.

Splenic artery aneurysms are most often asymptomatic. Symptomatic patients exhibit vague left upper quadrant or epigastric discomfort and occasional radiation of pain to the left shoulder or subscapular area. Most splenic artery aneurysms are less than 2 cm in diameter; therefore, a pulsatile mass is not palpable. Occasionally, a systolic bruit can be heard.

Only 2% of splenic artery aneurysms result in life-threatening rupture.31 More than 95% of ruptures occur in
young women during pregnancy and can be confused with ectopic pregnancy or placental abruption.

Splenic artery aneurysms are usually an incidental discovery on the abdominal radiograph as signet ring calcifications in the left upper quadrant. Ultrasonography, CT, and MRI can distinguish aneurysms from other cystic lesions in the left upper quadrant. An angiogram is usually required to confirm the diagnosis. Symptomatic splenic artery aneurysms require immediate operative intervention, particularly in pregnant women or in women of childbearing age. The rate of maternal mortality from rupture during pregnancy is approximately 70%. In asymptomatic patients, transcatheter embolization is an alternative to surgery.

**Hepatic Artery Aneurysms**

Hepatic artery aneurysms represent 20% of visceral artery aneurysms. The lesions are caused by atherosclerosis, infection (most often as a complication of IV drug abuse), major abdominal trauma, and polyarteritis nodosa. Hepatic artery aneurysms affect men twice as often as women and usually occur in patients older than 60 years of age.

Most aneurysms remain asymptomatic, but unruptured symptomatic aneurysms generally produce symptoms consistent with cholecystitis: vague, persistent, right upper quadrant or epigastric pain radiating to the back. Large aneurysms can cause severe upper abdominal discomfort, similar to pancreatitis. Hepatic artery aneurysms may rupture into the common bile duct, peritoneum, or adjacent hollow viscera. The mortality rate associated with hepatic artery rupture is 35%.

An abdominal bruit or palpable pulsatile mass is usually not present on physical examination. Aneurysmal calcification may be seen on a plain abdominal radiograph, but the diagnosis can be made reliably by angiography. Ultrasonography and CT can detect asymptomatic hepatic artery aneurysms.

Because of the high mortality rate with aneurysmal rupture, an aggressive approach to management is warranted. Surgical resection of the aneurysm is performed in operative candidates. Transarterial catheter occlusion can be used in patients who have high surgical risks.

**Superior Mesenteric Artery Aneurysms**

Superior mesenteric artery aneurysms are the third most common visceral aneurysms. Nearly 60% are infected aneurysms caused by nonhemolytic streptococci from left-sided bacterial endocarditis. Atherosclerosis and trauma are much less common causes. Patients are usually younger than 50 years of age; men and women are affected equally.

Patients generally have intermittent upper abdominal pain consistent with abdominal angina. Fifty percent have a pulsatile abdominal mass on physical examination. The stigmata of subacute bacterial endocarditis may be present. Plain abdominal radiographs may show a calcified aneurysm. Angiography is necessary to confirm the diagnosis.

Management of superior mesenteric artery aneurysm should address any underlying infectious process. The surgical approach is difficult and varies with the condition of the patient, the shape of the aneurysm (saccular or fusiform), and the intraoperative assessment of bowel viability.

**Infected Aneurysms**

**Mycotic Aneurysms**

The term mycotic aneurysm has been a source of confusion in the medical literature. No direct association exists with fungal disease. Although the term has been used to describe any infected aneurysm regardless of cause, it should be reserved for infected aneurysms resulting from bacterial endocarditis, as originally described in 1885 by Osler.

Septic emboli from infective endocarditis implant in one of two ways. First, hematogenous seeding of bacteria can occur in nonaneurysmal arteries whose vessel walls have been damaged by preexisting atherosclerosis. Second, septic emboli can also become lodged in the vasa vasorum of larger vessels, causing vessel wall ischemia and infection. In smaller vessels, septic emboli tend to lodge at arterial bifurcations, arteriovenous fistulae, or sites of arterial stenosis. Mycotic aneurysms are most common in the aorta, superior mesenteric artery, and intracranial and femoral arteries.

The infecting organism in mycotic aneurysms reflects the bacteriology of infective endocarditis. *Streptococcus viridans* is the most common organism, although IV drug abusers are most often infected by *Staphylococcus aureus*. Patients who have mycotic aneurysms tend to be 30 to 50 years of age. The mortality rate is reported to be 25% (Table 85-2).

**Atherosclerotic Arteries**

Currently, the most common cause of an infected aneurysm is sepsis with hematogenous spread of bacteria, such as *Salmonella, Staphylococcus*, and *Escherichia coli*, to atherosclerotic

arteries. Large vessels (especially the aorta) rather than peripheral arteries are the most common site. Patients tend to be older than 50 and to have well-established atherosclerosis. Perforation often occurs before diagnosis and carries a mortality rate of 75%.

### Preexisting Aneurysms

The incidence of infection in patients with preexisting atherosclerotic aneurysms is estimated at 3 to 4%, and patients with ruptured aneurysms have a higher incidence of positive bacterial culture results than those who have elective surgical treatment of an asymptomatic aneurysm. Gram-positive organisms, especially Staphylococcus, predominate (60%). The rate of mortality is extremely high (90%) because of aneurysm rupture.

### Post-traumatic Pseudoaneurysms

Post-traumatic infected aneurysms result from invasive hemodynamic monitoring, angiography, and IV drug use. The most common artery affected is the femoral because of its involvement in groin injection. S. aureus is isolated in 30 to 70% of cases. Because of the more peripheral location and early identification, the mortality rate is low (5%).

The clinical presentation of an infected aneurysm varies with anatomic location and underlying pathophysiologic process. Patients with infected abdominal aneurysms are often misdiagnosed. Onset is usually insidious; low-grade fever may be present for several months. Common findings are fever (75%), back and abdominal pain (33%), and palpable aneurysm (53%). More peripheral aneurysms, especially infected femoral pseudoaneurysms, are characterized by a tender groin mass, some manifestation of sepsis, or bleeding. Almost all are easily palpable. Although rare, fungal infections should be considered in patients who are chronically immunosuppressed, have been treated recently for disseminated fungal disease, or have diabetes mellitus.

Positive blood cultures in a patient with a preexisting aneurysm should prompt treatment as an infected aneurysm until disproven. Bacteremia is often continuous, and blood culture findings are positive for bacterial growth in approximately 70% of cases, so negative blood cultures do not rule out this diagnosis. Angiography should be performed when an infected aneurysm is suggested. Indium-111-labeled white blood cells are used to confirm or rule out infected aneurysms.

Treatment includes both antibiotics and surgical repair. Antibiotic therapy is usually continued for at least 6 to 8 weeks, although some physicians advocate lifelong treatment after successful surgical repair. The most important intervention is timely repair. Without surgery, aneurysm rupture with exsanguinating hemorrhage is inevitable.

### Traumatic Aneurysms

**Traumatic aneurysm** refers to a pseudoaneurysm that follows perforation of the arterial wall, with formation of a perivascular hematoma. Chronic traumatic aneurysms may or may not be associated with an arteriovenous fistula. **Pseudoaneurysm** is a synonym for *false aneurysm*.

The usual presentation is a pulsatile mass found near the course of an extremity artery, with a history of trauma more than 1 month earlier. The expanding aneurysm may compress associated peripheral nerves and produce neuropathy. Distal perfusion is usually well maintained, and thromboembolism is rare. A loud systolic and possibly a separate faint diastolic murmur are characteristic.

The diagnosis can be verified with many methods, including conventional angiography, digital subtraction arteriography, and CT. Surgical excision of the aneurysm is indicated as soon as possible to decrease the risk of complications, including rupture, thrombosis, or neurologic dysfunction caused by continued expansion.

### VASOSPASTIC DISORDERS

Vasospastic disorders are characterized by an abnormal vaso-motor response in the distal small arteries. Blood flow in the peripheral circulation is controlled by local, autonomic, and humoral mechanisms. The cause of the heightened vasospastic response is unknown.

Raynaud’s disease is the most common vasospastic disorder and occurs five or more times as often in women as in men. By definition, cases of Raynaud’s disease have no evidence of an underlying cause. The diagnosis is correct in 95% of cases using these criteria: (1) episodes are precipitated by cold or emotion; (2) symptoms are bilateral; (3) gangrene is absent or is minimal and confined to the skin; (4) no disease or condition that could cause a secondary Raynaud’s phenomenon is present; and (5) symptoms have been occurring for at least 2 years.

The classic Raynaud’s attack is triphasic: the fingers become white, then blue, and finally red. This is produced initially by complete closure of the palmar and digital arteries (and possibly arterioles), producing cessation of capillary perfusion. When a slight relaxation of arterial spasm occurs, a slight flow of blood returns into the dilated capillary bed, where it rapidly dissipates, producing cyanosis. Arterial spasm usually spontaneously resolves, arterial flow returns to baseline, but reactive hyperemia produces a red extremity. Attacks are often precipitated by cold and emotional stress. Raynaud’s disease usually follows a benign course. True histologic changes within the vessel wall are absent. Reassurance, education, and continued primary care follow-up observation are the only treatment necessary for true Raynaud’s disease.

Raynaud’s phenomenon is Raynaud’s disease that has an identifiable underlying disorder. Connective tissue disorders, including scleroderma, rheumatoid arthritis, and systemic lupus erythematosus, have the highest association with Raynaud’s phenomenon. Treatment should be directed toward identifying the underlying disorder and minimizing threatened tissue loss if present.

Benign livedo reticularis is caused by spasm of the dermal arterioles and may involve all parts of the upper and lower extremities, including the trunk. It is most common when skin is exposed to a cool environment. It is never associated with histologic vascular abnormality and quickly resolves when the exposed skin is covered or the environment is warmed. Other conditions, similar to the causes of Raynaud’s phenomenon, can have secondary livedo reticularis along with other peripheral vascular disease manifestations.

Acrocyanosis is the least common of the vasospastic disorders and is characterized by persistent, painless, symmetrical cyanosis of the fingers, the hands, and less often the feet. The disease is benign and not associated with either vascular abnormality or an underlying disorder. Pain, trophic skin changes, and ulceration do not occur. This disorder occurs more often in women, is intensified by exposure to cold, and decreases with warming. The diagnosis is made by the bilateral and persistent nature of the findings, localized to the hands or feet in the presence of normal arterial pulses. The involved extremities are nearly always cold and excessive perspiration is common. Except for reassurance and protection from cold, treatment is usually unnecessary.
Primary erythromelalgia is a rare syndrome of paroxysmal vasodilation with burning pain, increased skin temperature, and redness of the feet and less often the hands. However, secondary erythromelalgia can occur in patients with underlying disease processes, most often systemic lupus erythematosus, myeloproliferative disorders, hypertension, venous insufficiency, or diabetes mellitus. Erythromelalgia is as common in children as adults, but in children it is less likely to be associated with an underlying systemic illness. Attacks are not triggered by cold and usually occur during modest ambient temperatures. Skin temperature of the involved digits is high compared with the patient’s core temperature. Symptoms may remain mild for years or may become disabling. Tissue loss and trophic skin changes do not occur. Although rest, elevation of the extremities, and cold compresses or immersion in ice can provide temporary relief, no consistently effective treatment has been found for the multiple, often daily episodes of pain that occur with erythromelalgia.

### THORACIC OUTLET SYNDROME

Thoracic outlet syndrome involves compression of the brachial plexus, subclavian vein, or subclavian artery at the superior aperture of the thorax. Thoracic outlet syndromes were previously categorized by cause as scalenus anticus, costoclavicular, hyperabduction, cervical rib, and first thoracic rib syndromes. They are now most easily divided into three types—neurologic, venous, and arterial—depending on the predominant symptoms.

Compression of the brachial plexus causes the neurologic type of thoracic outlet syndrome and accounts for approximately 95% of all cases. Symptoms begin between the ages of 20 and 50 years, with women predominating at a ratio of about 3:1. Compression or thrombosis of the subclavian vein constitutes the venous type of thoracic outlet syndrome and is responsible for 4% of all cases. It occurs most often in men 20 to 35 years of age. The arterial type of thoracic outlet syndrome is rare, occurring in approximately 1% of all cases, but is potentially the most serious of the three types. Men and women are equally affected in a bimodal age distribution of young adults (from cervical rib compression) and patients older than age 50 (from localized atherosclerosis caused by arterial compression). Figure 85-3 demonstrates the relationship between anatomic abnormalities and neurovascular compression.

### Principles of Disease

Roos has described four basic concepts of thoracic outlet syndromes: (1) patients who have a thoracic outlet syndrome develop an anatomic abnormality predisposing them to symptoms under certain conditions; (2) brachial plexus compression or irritation constitutes approximately 95% of all thoracic outlet syndrome cases and is rarely caused by compression of the subclavian artery; (3) bedside testing for thoracic outlet syndrome based on positional compression of the subclavian artery is insensitive and unreliable; and (4) in advanced or refractory cases, the causative anatomic abnormalities must be surgically corrected.

The subclavian artery courses over the first rib between the scalenus anticus muscle anteriorly and the scalenus medius muscle posteriorly. From this point, it passes under the...
clavicle to the axilla, where the brachial plexus lies posteriorly and laterally. Four anatomic abnormalities have been associated with thoracic outlet syndrome.

Cervical rib syndrome results from an uncommon abnormality (0.5–0.7% of all chest radiographs), which is bilateral in 70% of patients. It occurs twice as often in women as men. Most cervical ribs are incomplete, attached to a fibrous band on the scalene tubercle of the first rib. The site of compression is the scalene hiatus, made up of the scalene anterior muscle frontally, the scalene medius posteriorly, and the cervical rib inferiorly.

Scalenus anticus syndrome results when the neurovascular bundle is compressed by various insertions of the anterior scalene muscle as it passes through the interscalene triangle. In some patients, the subclavian artery passes through the body of the muscle.

Costoclavicular syndrome results when the shoulders are moved backward and downward. Causes include hypertrophy of the subclavious muscle, abnormalities of the first rib, and past clavicular fractures.

Hyperabduction syndrome results from the neurovascular compression that occurs when the arms are placed in the hyperabducted position. The site of compression is in the retroclavicular space anterior to the first rib or at the point where the neurovascular bundle passes beneath the pectoralis minor muscle.

The neurologic and venous compression type of thoracic outlet syndrome can be associated with any underlying anatomic abnormality. Bony abnormalities (cervical rib, first thoracic rib, or clavicle) are the most common causes of the arterial type of thoracic outlet syndrome (Fig. 85-4A).

Clinical Features

Compression or irritation of the brachial plexus most often affects the lower two nerve roots, eighth cervical (C8) and first thoracic (T1), producing pain and paresthesias in the ulnar nerve distribution. The second most common anatomic pattern is involvement of the upper three nerve roots of the brachial plexus (C5, C6, and C7), with symptoms referable to the neck, ear, upper chest, upper back, and outer arm in the radial nerve distribution. Venous compression eventually progresses to intimal damage and subclavian vein thrombosis, with venous engorgement and swelling of the affected extremity. Persistent subclavian artery compression eventually results in poststenotic aneurysm formation and its sequelae.

Physical Examination

The Adson, costoclavicular, and hyperabduction maneuvers are unreliable as diagnostic tests. The most reliable test in screening for thoracic outlet syndrome is the elevated arm stress test (EAST). With the patient sitting, the arms are abducted 90 degrees from the thorax and the elbows flexed 90 degrees, with the shoulders braced slightly behind the frontal plane. The patient is asked to open and close the fists slowly but steadily for a full 3 minutes and to describe any symptoms that develop. Normal patients perform this test without symptoms other than mild fatigue. The patient with thoracic outlet syndrome, however, usually has early heaviness and fatigue of the involved limb, gradual onset of numbness of the hand, and progressive aching through the arm and top of the shoulder. Within the 3 minutes, the patient usually drops the hand to the lap for relief of the progressive, crescendo distress that becomes intolerable. Patients with carpal tunnel syndrome may experience dysesthesias in the fingers but do not have shoulder or arm pain. Patients with cervical disk syndromes may have pain in the neck and shoulder but have no arm or hand symptoms.

The EAST evaluates all three types of thoracic outlet syndrome: neurologic, venous, and arterial. Radial pulses can be palpated by the examiner during the test. The presence of a radial pulse and a positive EAST test result are strong indications that the basis of symptoms is neurologic involvement of the brachial plexus.

The hands should be observed for changes in skin color, warmth, moisture, or muscular atrophy. Triceps muscle strength (innervated by C7) should be tested bilaterally. Muscle strength of the interosseous muscles (innervated by C8 and T1) should be tested by asking the patient to spread the fingers apart against resistance. The muscles innervated by the radial nerve are tested by the patient hyperextending the thumb and dorsiflexing the wrist against resistance. The median nerve innervates the thenar muscles, which can be tested by asking the patient to abduct the thumb away from the palm with the thumb pointing straight to the ceiling. Tinel’s sign (“electric shock” to tips of fingers) is an indication of carpal tunnel compression of the median nerve and is elicited by percussing the volar aspect of the wrist. Gentle pressure with the thumb in the supraclavicular fossa over the brachial plexus may reproduce thoracic outlet symptoms after several seconds. The cervical spine and upper extremity reflexes should be assessed.

A blood pressure difference between the two arms is a reliable indication of arterial involvement. The blood pressure in the affected arm is lower. Doppler ultrasonography may be helpful in demonstrating comparatively reduced pressure over the pairs of radial, ulnar, and brachial arteries. The supraclavicular area should be auscultated bilaterally for subclavian bruits.

Ancillary Evaluation

Cervical spine radiographs with oblique views and chest radiographs are indicated in each patient for evaluation of skeletal abnormalities (first rib, cervical rib, clavicle deformity), trauma, arthritis, scoliosis, Pancoast's tumor, or other pulmonary disease. Neurologic studies, including electromyography, nerve conduction times, and somatosensory-evoked potentials, are generally unreliable and do not provide objective evidence of thoracic outlet syndrome. Patients thought to have cervical disk or spinal cord disease may require cervical myelography, CT, or MRI.

Arteriography is recommended with (1) obliteration of radial pulse on the EAST, (2) blood pressure 20 mm Hg less than that of the opposite asymptomatic limb, (3) possible subclavian stenosis or aneurysm (bruit or abnormal supraclavicular
Differential Diagnosis

The correct diagnosis of thoracic outlet syndrome can usually be made with clinical examination alone. A constant systolic and diastolic (to-and-fro) murmur associated with a palpable thrill is characteristic. Sixty percent of arteriovenous fistulae are also associated with a coexisting false aneurysm. Patients with peripheral venous disease may have similar cutaneous manifestations (varicose veins and stasis pigmentation) but lack vascular bruits. Infection in the form of bacterial endarteritis may complicate large fistulae.

Management

Acquired peripheral arteriovenous fistulae usually increase in size with time if surgery is delayed. Vessel dilation, peripheral ischemia, and cardiac output increase. Transcatheter embolectomy with detachable balloons and liquid acrylic tissue adhesives (e.g., isobutyl 2-cyanoacrylate) is used for surgically inaccessible fistulae.

VASCULAR ABNORMALITY CAUSED BY DRUG ABUSE

Principles of Disease

The vascular complications of parenteral drug use have risen significantly in both frequency and severity since the late 1980s. These IV or intra-arterial injuries can result in acute arterial ischemia, infected pseudoaneurysms, lymphatic obstruction, or direct neurologic injury.

Acute arterial ischemia results from direct drug effects or endogenous catecholamine release after injection. Endothelial wall damage can stimulate platelet aggregation and thrombus formation. Precipitated crystals, talc, or foreign body emboli can cause arterial occlusion. Necrotizing arteritis can produce ischemia and is especially prevalent in patients who abuse IV methamphetamines.

Infected pseudoaneurysms associated with arteriovenous fistulae result from a through-and-through puncture of the artery with simultaneous contamination from either skin flora or organisms inoculated by contaminated needles or drug. These fistulae are the most common vascular lesions resulting from IV drug abuse. Secondary infection of the vascular structure may be covered by a surrounding soft tissue infection (cellulitis or abscess). Infected aneurysms at sites distant from the injection can occur.

Intravenous drug abusers can develop unilateral hand edema or “puffy hand syndrome” because of gradual obliteration of the superficial venous vessels and chronic lymphatic obstruction. Direct injury to adjacent nerves, polymyositis, and ischemic neuritis can result from IV drug abuse. Coexisting infections include cellulitis, septicemia, and bacterial endocarditis.

Clinical Features

Patients may withhold information about the use of IV drugs, but objective evidence such as track marks may be present. Distal ischemia after intra-arterial injection most often occurs in the upper extremity after injection of the brachial or radial artery. The immediate onset of a severe, burning pain at the time of injection is a characteristic hallmark. Patients have a painful, edematous upper extremity with patchy blue-purple
skin discoloration. Distal pulses are generally present, but the skin temperature of the involved extremity is decreased. Because patients tend to seek attention early, the site of injection may be identifiable over the radial or brachial artery. Evidence of gangrene, pregangrenous changes, or neuromuscular deficits may accompany this syndrome.

Patients with infected pseudoaneurysms have a painful mass develop several days to weeks after injection, with resultant bleeding or “hitting pink.” The mass is usually pulsatile, and 50% have an associated bruit. Infected pseudoaneurysm is part of the differential diagnosis of cutaneous abscess or cellulitis in an IV drug user. Infected pseudoaneurysms are most often encountered in the lower extremities (80%). All patients should be carefully evaluated for sepsis, metastatic infection, and bacterial endocarditis. A peripheral vascular examination with careful documentation of pulses should be performed. A radiograph of the affected extremity can detect subcutaneous needle or foreign body. Angiography is the diagnostic procedure of choice for suggested pseudoaneurysm or distal ischemia. Ultrasonography is often unable to distinguish an aneurysm from an abscess or cellulitis.

**Management**

Therapeutic considerations for acute ischemia from intra-arterial injection are primarily conservative. Intra-arterial vasodilators, heparin, low-molecular-weight dextran, fibrinolytic therapy, analgesics, systemic warming to stimulate vasodilation, antibiotics, elevation of the affected limb to promote venous drainage, and physical therapy have not significantly altered the outcome or amputation rate in this patient population. Surgical treatment is reserved for delayed amputation, with the goal of preserving as much tissue as possible. Gradual resolution of symptoms without surgical intervention is the most common outcome.

Patients with infected pseudoaneurysms require aneurysm resection, débridement of infected tissue, and ligation of the proximal and distal uninfected arteries. Autogenous vein bypass through uninfected tissue planes may require an extensive surgical approach. Intravenous nafcillin is recommended for mild infections, nafcillin and a second- or third-generation cephalosporin for major infections, and vancomycin and a second- or third-generation cephalosporin or an aminoglycoside for patients who are bacteremic or overtly septic. Methicillin-resistant *S. aureus* and gram-negative rods are increasing in frequency as the causative agents in infections and vascular injury resulting from drug abuse, and vancomycin should be added if these organisms are suggested.

### PROBLEMS RELATED TO LONG-TERM CENTRAL VENOUS ACCESS

#### Hickman-Broviac Catheter

The Hickman-Broviac double-lumen catheter is in common use, with the smaller Broviac line used for the administration of IV therapy and the larger Hickman line reserved for additional venous access and blood withdrawal (Fig. 85-5; see also Fig. 85-7B). This catheter is generally inserted into the cephalic, subclavian, external, or internal jugular vein, with the distal tip just above the right atrium. The proximal end exits through a subcutaneous tunnel from the lower anterior chest wall. A felt cuff (Dacron) is used to anchor it in place subcutaneously. The Hickman-Broviac catheter is made of polymeric silicone rubber that is of low thrombogenic potential but extremely flexible and soft. Because of the pliability of the material, the catheter must be treated gently. Clearing an obstructed catheter with a guidewire may perforate the catheter. Forcing fluid through the catheter by positive pressure carries the risk of catheter rupture or catheter embolus. For this reason, no syringe larger than 5 mL should be used for irrigation.

#### Routine Care and Use

The smaller Broviac line is most often used for the infusion of total parenteral nutrition or fat emulsions. This line should be irrigated with 6 mL of normal saline solution between different infusions to prevent mixing of incompatible solutions, development of precipitation, and resultant catheter occlusion. The larger Hickman line should be used to withdraw blood. This line should be irrigated with 6 mL of heparinized saline.
after blood withdrawal to prevent clot formation in the catheter lumen. When a clamp is used, it should be placed over a piece of tape wrapped around the line. The clamp should have a smooth surface, since teeth or prongs could sever or abrade the line.

Routine care and frequency of catheter dressing changes vary with the preference of the treating physician. Most patients become skilled in routine catheter maintenance and are a reliable source of information. Absolute sterile technique is essential when manipulating the catheter.

Catheter Occlusion

Hickman catheters can exhibit complete or partial obstruction to flow in either line. Complete obstruction, in decreasing order of frequency, results from (1) clots within the catheter lumen, (2) precipitates within the catheter lumen, and (3) mechanical obstruction. In catheters that accept infusions at normal rates but cannot be aspirated, the causes, in decreasing order of frequency, are (1) catheter lodged against the wall of the vessel, (2) occluding fibrin sheath around the catheter tip, (3) ball valve or mural thrombus, and (4) central venous thrombosis. Patients who have intermittent complete occlusion and withdrawal occlusion have a type of mechanical obstruction called pinch-off syndrome, in which the catheter lumen is compromised from mechanical forces acting on it between the clavicle and the first rib. Clots within the catheter lumen, obstructing fibrin sheaths, and ball valve or mural thrombus often respond to low-dose intracatheter urokinase; central venous thrombosis, precipitants in the catheter lumen, and mechanical obstruction do not respond (Box 85-1).

Precipitants within the catheter lumen most often result from flushing the line with a heparin solution instead of saline after total parenteral nutrition. Heparin precipitates with total parenteral nutrition fluids. Clots within the catheter lumen usually result from failure to flush the line with a heparinized saline solution after blood aspiration.

A chest radiograph should be obtained in all patients with persistently occluded catheters to confirm catheter position and integrity. The catheter tip should be positioned just above the right atrium. Persistent right atrial placement can cause perforation of this thin-walled heart chamber or result in a right atrial thrombosis. Comparison with previous radiographs may be necessary to ensure lack of movement or displacement. In patients with withdrawal occlusion but appropriate catheter position and without clinical evidence of subclavian vein thrombosis, the catheter may be lodged against the vessel wall. The patient’s changing body position, raising the arms above the head, or performing the Valsalva maneuver may relieve withdrawal occlusion. If this is unsuccessful, some occlusions respond to low-dose intracatheter urokinase (see Box 85-1). Urokinase (5000 U) should be injected into the catheter and left for 30 minutes before aspiration is attempted. If this is also unsuccessful, a second dose of urokinase can be injected and the procedure repeated. While contraindications to fibrinolytic agents should be considered, low-dose therapy for occluded catheters appears to be well tolerated.

In the pinch-off syndrome the catheter is intermittently obstructed during both administration and withdrawal of fluids, typically within 3 weeks after catheter placement. A chest radiograph demonstrates narrowing of the catheter lumen as it passes between the clavicle and the first rib. The catheter must be removed because of fragmentation or embolization if left in place.

Because engorged collateral circulation or swelling in the affected extremity is not universally present with subclavian vein thrombosis, this diagnosis should be considered in all patients who are unresponsive to clotting attempts. Catheter removal with systemic heparinization or catheter maintenance with high-dose fibrinolytic therapy is a therapeutic option for subclavian vein thrombosis. Mechanical occlusion is rare and requires catheter replacement with a surgical approach. Because of variations in approach, early consultation is recommended in patients who have occluded central venous catheters (Fig. 85-6).

Catheter Laceration

If an external catheter laceration or fracture occurs, the catheter should be clamped over tape distal to the laceration close to the chest wall. The catheter can be repaired as long as the damage is more than 4 cm from the chest wall. After clamping, as an interim measure, the next step is to insert a 14-gauge, 2-inch shielded IV catheter (Angiocath) into the catheter; remove the stylus; tape securely; and flush with heparin. The catheter can then be used while a repair kit is obtained.

Catheter-Related Infections

Catheter infections can be categorized as local or systemic. Local infections primarily involve the skin and subcutaneous tissues surrounding the exit site with erythema, tenderness, and no clinical or laboratory evidence of sepsis. Skin organisms are primarily responsible for local infections, especially coagulase-negative staphylococci. Studies show that local infections usually do not require catheter removal and resolve with antimicrobial therapy alone.

The source of systemic infection in patients with Hickman-Broviac catheters may be difficult to localize, particularly in immunosuppressed patients. The most common sites of systemic infection in any patient with a central venous catheter, in decreasing order of frequency, are the urinary tract, the anorectal area, the upper respiratory tract, and the catheter. The most common organisms causing catheter infection are coagulase-negative staphylococci, S. aureus, and Candida albicans. In immunocompromised patients with Hickman-Broviac catheters, gram-positive organisms now are responsible for more cases of sepsis than gram-negative bacteria. Accordingly, initial empiric therapy should include an antistaphylococcal drug, in addition to the usual gram-negative coverage. A good empirical regimen is cefazolin (Ancef) (1 g) and gentamicin (1 mg/kg IV). All patients who have a possible vascular access infection should have two blood culture samples drawn. Comparison of blood culture samples drawn simultaneously through

*Usually responds to low-dose intracatheter urokinase.
the catheter and from a peripheral blood vessel may assist in determining whether the catheter is the source of infection. Infections that do not extend through the vessel wall (pericatheter infections) can be successfully treated without catheter removal. Catheter removal is mandatory in patients with continued positive blood culture results despite therapy and in those with vascular access infections caused by Candida species.61 Catheter-related septic central venous thrombosis can progress through and around the vessel wall to cause a perivascular infection or abscess. This rare but devastating complication is associated with serious morbidity and a reported mortality rate as high as 83%. Because of the lack of specific clinical findings, the most prominent diagnostic feature is continued bacteremia after catheter removal. Diagnosis is confirmed by venography or CT.62 Removal of the catheter, IV administration of antimicrobials, and anticoagulation constitute appropriate initial therapy. Surgical treatment with thrombectomy and possible abscess drainage are indicated after failure of an adequate course of antibiotics and anticoagulation. Fibrinolytic agents have been used as an adjunct for catheter-related septic venous thrombosis, but the risk-benefit ratio has not been established.63 In patients who require catheter removal, a quantitative culture of the number of organisms on the catheter’s surface correlates well with a positive blood culture result for the same organism. This technique involves rolling the catheter on a culture medium. Broth culture of catheter tips may be less reliable in determining whether the catheter is the source of infection.64

Groshong Catheter

The Groshong catheter is a single, thin-walled silicone rubber catheter designed for prolonged venous cannulation. It differs from the Hickman-Broviac catheter in insertion, design, and maintenance. A decreased outer diameter to inner diameter ratio allows insertion into a smaller vein through a smaller introducer sheath. The catheter can be inserted under local anesthesia without fluoroscopy, using the Seldinger technique and a peel-away catheter introducer sheath. After catheter placement in the subclavian, internal, or external jugular vein, a subcutaneous tunnel is created with a stainless steel
tunneling device through which the catheter is threaded. A Dacron cuff stabilizes the catheter’s placement in subcutaneous tissues and reduces the chance of inadvertent removal or retrograde infection. 65

The Groshong catheter is constructed with a closed end and a vocal cord–type integral valve at the distal end (Fig. 85-7A). This pressure-sensitive two-way valve at the intravascular end minimizes back-bleeding, eliminating the need for heparin flushes or external clamping, but permits blood sampling with gentle negative pressure. Patency of the catheter is maintained with 5 mL of saline flush once a week. A 20-mL saline irrigation is necessary after any blood transfusion or if blood is observed in the catheter lumen. A 30-mL saline irrigation is performed before blood sampling after infusion of hyperalimentation solutions.

Groshong catheters offer the advantage of bedside placement, minimal back-bleeding, elimination of heparin flushes, and elimination of external clamping when changing injection caps or connecting tubing. A lower incidence of complete obstruction to flow from clots or precipitates within the catheter lumen, however, has not been shown. 66 Groshong catheters are otherwise subject to the same complications as Hickman-Broviac catheters.

**Vascular Access for Hemodialysis**

**Quinton-Mahurkar Catheter**

The Quinton-Mahurkar catheter is the preferred catheter for providing immediate and short-term vascular access for hemodialysis. Its advantages include bedside placement and a functional life up to 18 months. 67 This single, flexible, polyurethane cannula has two separate D-shaped channels, each connected by a molded Y piece to a color-coded external port (Fig. 85-5B). To protect against a disconnected cap, each limb of the Y piece has an attached clamp. The Quinton-Mahurkar catheter is placed by the Seldinger technique, most often in the subclavian vein and less often in the femoral vein. The catheter is placed under sterile conditions, with careful perforation of the superficial wall of the femoral artery and the saphenous vein. Lower extremity arterial bridges have a higher blood flow rate and are less likely to thrombose but also have a higher rate of infection because of their proximity to the bacteria-laden perineum.

**Thrombosis**

Thrombosis is the most common complication of a subcutaneous arteriovenous fistula or prosthetic graft. It is important to avoid circumferential bandages, tourniquets, or blood pressure cuffs in the fistula-bearing arm because restricted venous outflow may predispose to thrombosis. A tourniquet should not be used. The opposite arm or the fistula itself can be used to acquire blood or vascular access (without using a tourniquet). Normal graft flow is clinically verified by feeling a thrill or hearing a bruit on auscultation. A strong palpable pulse with no matching thrill suggests venous outflow obstruction or early graft thrombosis. Thrombosis of arteriovenous fistulae requires temporary vascular access and usually the creation of a new fistula proximal to the thrombosed shunt.

**Blood Withdrawal**

Ideally, an alternative peripheral venipuncture site should be sought first before using a Cimino-Brescia fistula for blood withdrawal. When an alternative site is unavailable, however, the arteriovenous fistula is a reasonable choice. An individual skilled in venipuncture techniques should maintain absolute sterility with antiseptic (e.g., povidone-iodine [Betadine]) skin preparation, sterile gloves, and sterile gauze. Tourniquets are contraindicated and unnecessary. Venipuncture should be performed on the well-developed venous side of the fistula. After blood acquisition, gentle pressure should be maintained for 5 minutes, with care taken not to occlude the vessel lumen. The site should then be observed for several minutes to ensure that bleeding does not occur. A prosthetic arteriovenous bridge fistula can also be used to obtain blood samples with careful perforation of the superficial wall of the prosthetic graft; otherwise, the technique is identical.

Clinically differentiating a Cimino-Brescia fistula from a prosthetic arteriovenous bridge fistula may be difficult. The prosthetic portion of an arteriovenous bridge fistula connects the arterial to the venous vessels in an H shape and is tunnelled
for some distance beneath the skin, giving the appearance of a single, large blood vessel. The prosthetic fistula has a thrill but is not as pulsatile as a Cimino-Brescia fistula when gently palpated. If asked, most patients are knowledgeable about their fistula.

Peripheral IV access is best established at an alternative site. When an alternative site is unavailable and the patient requires timely IV access, the Cimino-Brescia fistula or bridge fistula can be used, following the guidelines for venipuncture. Careful attention to sterile technique, operator skill, and avoidance of tourniquets can provide timely venipuncture or IV therapy while preventing infectious or thrombotic complications. If an IV line is used in a fistula, early removal after alternative IV access is desirable.

Infection

Infections of an arteriovenous fistula or graft are potentially life-threatening and manifest with signs of septicemia and local inflammation. Once the diagnosis of infected fistula is considered, blood cultures should be obtained and IV antibiotics for gram-positive skin organisms administered. Prosthetic graft infection cannot be eradicated with IV antibiotics alone and requires prosthetic graft removal. Infections are the second leading cause of death of patients undergoing long-term dialysis.

Steal Phenomenon

Vascular steal from the ulnar artery via the palmar arch occasionally occurs in patients with atherosclerotic disease distal to the shunt, particularly diabetic patients. Symptoms of fingertip ischemia occur during periods of increased shunting (hemodialysis or increased activity). The steal phenomenon usually requires graft ligation with construction of a new fistula in the opposite extremity.

Venous Hypertension

Acute venous hypertension may occur in the first few weeks after fistula construction. This is a true surgical emergency. The early rise in venous pressure produces marked swelling of the extremity and severe venous stasis disease. Characteristic skin pigmentation, edema, and occasionally venous ulceration are seen. Management of venous hypertension requires hospitalization and urgent ligation of the vein immediately distal to the fistula before a potentially exsanguinating vessel rupture occurs.

Bleeding

Patients also present to the emergency department with bleeding from their fistula after dialysis. Persistent, gentle pressure, with care taken not to occlude blood flow, usually resolves this problem.

**KEY CONCEPTS**

- Acute arterial occlusion is a limb-threatening emergency requiring early heparinization and Fogarty catheter embolectomy. The clinical diagnosis is based on some variant of the “five P’s”: pain, pallor, pulselessness, paresthesias, and paralysis. Confirmatory tests are unnecessary and increase the limb’s ischemic status.
- Atheroembolism (blue toe syndrome) is associated with cool, painful cyanotic toes in the presence of palpable distal pulses. A proximal source should be localized, most often an atherosclerotic aneurysm in the aorta or the iliac, femoral, or popliteal artery.
- Popliteal aneurysms are bilateral in 60% of patients and often coexist with an abdominal aortic aneurysm.
- The classic Raynaud attack is triphasic: the fingers become white, blue, then red. Raynaud’s disease has no detectable underlying cause and usually has a benign course. Raynaud’s phenomenon has an underlying disorder, usually connective tissue disease.
- The only reliable clinical test for detection of thoracic outlet syndrome is the elevated arm stress test (EAST).
- The most common sites of systemic infection in patients with long-term central venous catheters are the urinary tract, the anorectal area, the upper respiratory tract, and the catheter, in that order. Local skin infection at the catheter site without systemic signs or symptoms usually responds to antibiotics and does not require catheter removal.
- Acute venous hypertension can occur in the first few weeks after construction of an arteriovenous fistula. Hospitalization is required for ligation of the vein before a potentially exsanguinating vessel rupture occurs.

PERSPECTIVE

This chapter discusses the diagnosis and treatment of venous thromboembolism (VTE), including deep vein thrombosis (DVT) and pulmonary embolism (PE), from the perspective of the emergency physician and provides a functional resource for the evaluation and treatment of VTE in the emergency department (ED).

Pathophysiology of Thrombosis

Timely diagnosis and treatment of VTE can be facilitated by understanding the pathophysiology of thrombosis. VTE represents the end product of imbalanced clot formation versus clot breakdown. Fibrin represents the primary structural framework of embolized clots, and excessive fibrin deposition represents the primary nidus of VTE. Fibrinogen converts to fibrin in response to vascular injury and inflammation. Vascular injury exposes tissue factor that promotes fibrin formation, and inflammation increases the production of fibrinogen, stimulating fibrin deposition. Factors that enhance fibrin formation include systemic inflammation (which includes almost all so-called acquired states of hypercoagulability, such as antiphospholipid antibody syndromes) and genetic thrombophilias and neoplastic abnormalities that increase fibrin formation or decrease fibrinolysis. In particular, sluggish blood flow in large veins permits the process of fibrin deposition. Rudolf Virchow, a 19th-century pathologist, recognized the triad of venous injury, slow blood flow, and hypercoagulability as the cardinal factors that classify a patient as being at risk for excessive fibrin deposition relative to fibrin removal. Most clinical decision rules for VTE incorporate these factors to help decide who has VTE and who does not. Despite its simplicity and elegance, from the perspective of diagnosis, Virchow's triad does not include the crucial issues of age or physiologic effects of VTE.

Epidemiologic studies show convincingly that age increases the likelihood of imbalanced clot formation. Aging leads to venous valvular incompetence, which impairs venous return, and causes blood stasis; aging also increases the probability of an acquired hypercoagulability, such as malignancy. Older patients have more cumulative effects of inflammatory damage to venous endothelium; are more likely to be exposed to the independent risk factor of surgery; and may be predisposed to dehiscence, which probably accelerates clot deposition. Older patients have more heart and lung disease, and when PE is present, older patients are far more likely to manifest the adverse physiologic consequences of PE than younger patients with the same degree of thrombosis.

DEEP VEIN THROMBOSIS

DVT represents a disease spectrum ranging from a minimally symptomatic isolated calf vein thrombosis to a limb-threatening iliofemoral venous obstruction. Although the true incidence is unknown in the ED population, DVT accounts for approximately 600,000 hospital admissions per year.

Anatomy

The venous anatomy of the lower extremity can be divided into the deep and superficial systems. The superficial venous system consists primarily of the greater and short saphenous veins and the perforating veins. The deep venous system includes the anterior tibial, posterior tibial, and peroneal veins, collectively called the calf veins. The calf veins join together at the knee to form the popliteal vein, which extends proximally and becomes the femoral vein at the adductor canal. The femoral vein sometimes is called the superficial femoral vein, and this nomenclature may contribute to some confusion when interpreting radiology reports. A clot in the superficial femoral vein is indeed a DVT and should be treated as such. The femoral vein joins with the deep femoral vein to form the common femoral vein, which subsequently becomes the external iliac vein at the inguinal ligament. Proximal DVT refers to a clot in the popliteal vein or higher, whereas distal clot refers to an isolated calf vein thrombosis.

Clinical Presentation

The initial symptoms of DVT can be as subtle and nonspecific as a mild cramping sensation or sense of fullness in the calf, without objective swelling, and may be difficult to differentiate clinically from myriad other unrelated disorders (Box 86-1). It is precisely at this early stage, however, that DVT can be treated most effectively to minimize the potential morbidity and mortality associated with VTE. Likewise, the clinical signs of DVT vary and may include unilateral swelling, edema, erythema, and warmth of the affected extremity; tenderness to palpation along the distribution of the deep venous system; dilatation of superficial collateral veins; and palpable venous “cord.” The classic Homan’s sign (pain felt in the calf or posterior aspect of the knee on passive dorsiflexion of the foot
while the knee is extended) is insensitive and nonspecific for DVT and has no place in modern medicine.

**Diagnosis**

Estimation of the pretest probability (PTP) of DVT is the initial step in the diagnostic strategy. This estimation may be accomplished either by the clinical gestalt of an experienced practitioner or in conjunction with a clinical decision tool, such as that derived and validated by Wells and colleagues (Table 86-1) to determine which patient is at low risk.

**Laboratory Evaluation**

The D-dimer is a protein derived from enzymatic breakdown of cross-linked fibrin, and an elevated plasma concentration indicates the presence of a clot formed somewhere in the body within the past 72 hours. D-dimer concentration may be elevated with any condition that causes fibrin deposition, including malignancy, pregnancy, advanced age, prolonged bedrest, recent surgery, infection, inflammation, new indwelling catheters, stroke, and myocardial infarction. D-dimer concentration is proportionate to the size of the clot and decreases as the clot matures, so the test is less sensitive with small or chronic clots. D-dimer analysis may be useful in the evaluation of suggested DVT, but differences in D-dimer assay methodology can greatly affect diagnostic accuracy.

The D-dimer protein can be measured in plasma using several techniques. All commercially available assays share the concept of antibody capture followed by detection. As of July, 2008, the FDA has approved 43 different D-dimer assays, which employ varying capture antibodies and detection methods. One way to categorize the D-dimer assay format is as quantitative or qualitative (which includes semiquantitative assays). The two most common detection methods for quantitative assays are the enzyme-linked immunosorbent assay (ELISA) and the immunoturbidimetric technique. Because of variable properties of the test capture antibody and differences in test standardization, the quantitative D-dimer assays vary regarding their cutoffs for the upper limit of normal. For many assays, a concentration of less than 500 ng/mL is a negative test, and this test generally carries an 88 to 97% diagnostic sensitivity for symptomatic proximal DVT and 83 to 94% sensitivity for calf DVT or asymptomatic proximal DVT. A negative quantitative D-dimer assayed by the ELISA or immunoturbidimetric technique may be used to exclude the diagnosis of DVT in patients at low or moderate risk without further evaluation. Qualitative D-dimer assays include whole-blood assays done on single-use cartridges that resemble home pregnancy tests and semiquantitative latex fixation assays that employ test cards containing several wells for plasma in various folds of dilution. Qualitative D-dimer assays have a diagnostic sensitivity of 78 to 93% for symptomatic proximal DVT. As a result, a negative qualitative D-dimer excludes proximal DVT only in patients deemed to have a low clinical possibility by the physician.

**Radiographic Evaluation**

Contrast venography was once the gold standard for evaluating DVT, but it has largely been supplanted by a combination of D-dimer testing and duplex venous ultrasonography. Venography has the advantage of being able to differentiate between an acute and chronic thrombus, but clinical presentation usually provides this differentiation, so the test is rarely indicated on this basis.

Venous duplex ultrasonography, performed by a certified sonographer and interpreted by a board-certified radiologist or similarly credentialed expert, has a sensitivity and specificity of approximately 95% for proximal DVT and is the diagnostic test of choice in most centers. A patient at low risk may have the diagnosis of DVT effectively excluded by a single negative test. A patient who is not at low risk should prompt further testing. A patient with a moderate or high PTP, a negative ultrasound, and a negative quantitative D-dimer has DVT excluded. If the D-dimer is elevated (or not performed), a patient with a moderate or high PTP and a negative ultrasound at the index visit can have DVT excluded after a repeat ultrasound that is negative for DVT in 2 to 7 days. An expertly performed and interpreted positive ultrasound is sufficient to confirm the diagnosis of DVT. Ultrasound cannot sufficiently image the pelvic veins or vena cava, but may identify a tangible alternative diagnosis, such as a ruptured Baker’s cyst.

Many emergency physicians utilize bedside ED ultrasound in their daily practice for a variety of indications. A recent meta-analysis comparing emergency physician-performed...
ultrasound (EPPU) for lower-extremity DVT with radiology-performed ultrasound studies calculated an overall sensitivity of 95% (95% confidence interval [CI] 87–99%) and specificity of 96% (95% CI 87–99%). Although these results appear favorable, issues involving training and prior experience raise questions about the generalizability of these findings. A follow-up prospective study of EPPU performed by a heterogeneous group of 56 emergency physicians revealed a sensitivity of 70% (95% CI 50–86%) and specificity of 89% (95% CI 83–94%), although the diagnostic accuracy was very good for operators who had performed more than three EPPU examinations (Fig. 86-1).8

Indirect computed tomography venography (CTV) is not a primary imaging modality for DVT, but may be performed in conjunction with CT pulmonary angiography (CTPA) of the chest during the evaluation of suggested PE. The technique involves imaging the pelvis and lower extremities during the venous return phase of the intravenous (IV) contrast material administered for the CTPA. Adding CTV to CTPA provides an incremental increase in the sensitivity for VTE, identifying DVT in approximately 2% of patients in whom the CTPA is read as negative for PE but at the expense of significant additional radiation exposure to the pelvis and lower extremities.6–10 Interobserver agreement among radiologists interpreting CTV appears to be less than that for the CTPA portion of the study.11 At this time, the overall clinical utility of CTV remains controversial.

Magnetic resonance imaging (MRI) can evaluate the pelvic vasculature and vena cava, which is not possible with ultrasound. MRI does not require exposure to ionizing radiation, making it an attractive option for pregnant patients with possible VTE. The clinical utility of MRI is currently limited by cost and availability.

Impedance plethysmography and strain-gauge plethysmography measure physical features of the leg (electrical resistance or girth) during venous outflow from the extremities to diagnose proximal DVT. The reported sensitivities are highly technique-dependent, and these tests are not recommended.

**Figure 86-1.** Graph showing the learning requirement for emergency physician-performed ultrasonography (EPPU). This figure plots the diagnostic results of each EPPU done by residents and attending physicians in a research study designed to measure the diagnostic accuracy for DVT. Each tile represents a unique clinician-participant (x-axis) who enrolled a unique patient-participant (y-axis), and each tile is color-coded to show the diagnostic result of the EPPU. The tiles are ordered from left to right in order of least to most number of patients enrolled per clinician. The tiles stack up vertically in temporal order. For example, the clinician to the far right enrolled a total of 20 patients: the first was a false positive, the fourth was a true positive, and the last seven were true negatives. This figure shows that the diagnostic sensitivity improved to 100% for clinicians who had enrolled at least three prior patients.

**Superficial Thrombophlebitis**

Although thrombophlebitis of the superficial veins uncommonly evolves into a thromboembolic event, many patients with clinically suggested superficial thrombophlebitis have a simultaneous DVT. Patients with a clot in the greater saphenous vein that extends above the knee are at risk for progression to DVT via the saphenous-femoral vein junction and should be considered for anticoagulation, although data are not available to quantitate the benefit (or harm). When DVT has been excluded, superficial thrombophlebitis should be treated symptomatically with nonsteroidal anti-inflammatory drugs, heat, and graded compression stockings (fitted to exert 30–40 mm Hg of pressure at the ankle). Increased ambulation and elevation of the extremity above the level of the heart while at rest help to decrease venous stasis. Routine anticoagulation is not indicated for superficial thrombophlebitis unless the patient is at extreme risk for developing clot extension, such as results in the presence of an external fixation device on the extremity, a proximal indwelling catheter, or from a very high risk thrombophilia such as an active adenocarcinoma or homozygous factor V Leiden genetic sequence variation.

**Treatment**

When the diagnosis of DVT has been established, anticoagulation should be initiated, unless contraindicated, with weight-based unfractionated heparin (80 U/kg IV bolus followed by 18 U/kg/h infusion) or a low-molecular-weight heparin (e.g., enoxaparin, 1 mg/kg subcutaneously every 12 hours) assuming normal renal function. Both forms of heparin work equally well, and both are safe in the absence of contraindications to anticoagulation. Treatment requires transition to oral anticoagulation with warfarin for at least 3 months. Hospital admission is obviated by initiation of outpatient enoxaparin therapy in the ED or ED observation unit, followed by self-administration at home (with appropriate patient teaching) or home administration by a visiting nurse. If admission is contemplated, the first dose of warfarin can be given in the ED to help reduce overall length of stay in the inpatient unit. Patients should be encouraged to ambulate after anticoagulation for DVT; bedrest represents an illogical measure for reducing the chance of clot dislodgement and development of PE because continued immobilization of the thrombosed extremity promotes DVT extension, increases the risk of embolization, and ultimately predisposes the patient to the postphlebitic syndrome.12 Patients who cannot be given anticoagulants and those who have a recurrence of VTE despite anticoagulation therapy should be considered for vena caval interruption.
Isolated Calf or Saphenous Vein Thrombosis

The optimal management strategy for thromboses of the saphenous, tibial, or peroneal veins remains controversial.\(^{13}\) Isolated calf vein thrombosis was, previously, thought to carry a low risk of embolization that did not warrant anticoagulation. Longitudinal studies subsequently found that approximately 25% of isolated calf vein thromboses propagate proximally, prompting many experts to recommend treatment with anticoagulation as for DVT.\(^{14}\) Others argue that a reasonable alternative in an otherwise healthy, ambulatory patient with an isolated calf thrombus and no other indication for anticoagulation is to prescribe antiplatelet therapy with aspirin (325 mg/day of enteric-coated acetylsalicylic acid) and arrange for close follow-up with serial duplex ultrasound scans at 2 to 7 days to evaluate for clot propagation.

Phlegmasia Cerulea Dolens (Painful Blue Leg)

Massive iliofemoral occlusion results in swelling of the entire leg with extensive vascular congestion and associated venous ischemia, producing a painful, cyanotic extremity. There may be an associated arterial spasm resulting in phlegmasia alba dolens (painful white leg or milk leg), which may mimic an acute arterial occlusion. Prompt consultation with a vascular surgeon should be obtained because patients with *phlegmasia cerulea dolens* may require emergent thrombectomy. If timely consultation is not possible, early thrombolytic therapy may be a limb-salvaging procedure in the absence of contraindications. One such strategy is to infuse alteplase (1 mg/min to a total dose of 50 mg) via a peripheral IV catheter placed distal to the thrombus.

Upper Extremity Venous Thromboses

DVTs of the upper extremity have become more common in association with increased prevalence of indwelling venous catheters and wires for electronic cardiac devices. Upper extremity DVT can cause PE, and all patients with DVT above the elbow require definitive treatment.\(^{15-17}\) Axillary vein clots have recently become a topic of intense research activity. Several thematic points appear to be emerging: (1) About one half of all upper extremity DVTs are associated with an indwelling catheter. (2) DVT does not automatically warrant catheter removal if the catheter serves a vital purpose. However, these patients should receive anticoagulation if they do not have contraindications. The duration of anticoagulation following catheter removal for DVT remains controversial, but most published guidelines recommend at least 3 months. (3) The rate of PE from axillary vein DVT appears to be similar to that for femoral vein DVT, although many experts believe the severity of PE tends to be less with upper extremity DVT. (4) Isolated upper extremity DVT, especially axillary-subclavian vein thrombosis, also can be seen in relatively young, active, otherwise healthy patients. Although standard DVT risk factors, such as hypercoagulable state or malignancy may be present, most of these patients have no apparent predisposing condition. The most prevalent theory now is that these patients have abnormal anatomy related to their thoracic inlet and that direct or indirect pressure on the upper extremity venous system leads to eventual thrombosis. It is not known whether strenuous, repetitive activity (the condition was once called “effort DVT”) causes the DVT by exacerbating the anatomic compromise through movement of the arm or hypertrophy of adjacent muscles, or whether effort simply brings out the symptoms of an otherwise occult upper extremity DVT. Many patients, however, engage in strenuous activities or sports involving the arm, and almost all will first experience their symptoms during a period of intense use of the arm and hand. Typically, patients present with an ill-defined ache or throbbing sensation of the affected extremity, distal swelling, or a sensation of arm heaviness, any or all of which are exacerbated by strenuous arm activity. Diagnosis is by a combination of clinical evaluation, D-dimer testing, and duplex ultrasonography. Venography is used primarily when surgical embolectomy or catheter lysis are contemplated. CT and MRI are of limited value. Treatment is by anticoagulation, possibly supplemented by catheter-directed fibrinolysis or embolectomy. Consultation with a vascular surgeon is advisable. Even with restoration of vein patency and long-term anticoagulation (as for a lower extremity DVT), many patients will remain symptomatic after 5 years, and some will have severe, permanent limitation of function.

Complications

Although the most feared complication of DVT is fatal PE, DVT damages venous valves, causing venous insufficiency. Venous insufficiency in turn, manifests as a spectrum ranging from painless varicosities to severe postphlebitic syndrome, which can cause unremitting pain and swelling, varicose veins, skin changes, and nonhealing ulcers.

PULMONARY EMBOLISM

PE results from a clot that formed hours, days, or weeks earlier in the deep veins that dislodges, travels through the venous system, traverses the right ventricle, and lodges in the pulmonary vasculature. During transit and after docking in the pulmonary vasculature, the embolism produces a highly variable set of symptoms and a wide range of physiologic perturbations. This variability contributes to the difficulty in diagnosing PE. No one knows exactly how many patients pass through the ED with PE because there is no reliable way of identifying missed cases. Assuming that ED populations have a risk for PE somewhere between hospitalized patients (who are at high risk for PE) and outpatients (who are at lower risk), approximately 1 in every 500 to 1000 ED patients has PE.\(^{19}\) About 10% of ED patients with PE die within 30 days even when PE is promptly diagnosed and treated.\(^{19,20}\)

Pathophysiology of Pulmonary Vascular Occlusion

The pulmonary vascular tree normally has a low resistance to fluid flow, and young persons without cardiopulmonary disease (e.g., congestive heart failure, chronic obstructive lung disease, advanced sarcoidosis, pulmonary fibrosis, scleroderma, and primary pulmonary hypertension) can tolerate at least 30% obstruction often with minimal trifling symptoms or signs. Pulmonary infarction is a more dramatic exception. Although a segmental pulmonary artery constitutes only about one sixteenth of the entire pulmonary vascular circuit, a clot lodged deeply in a segmental artery can obstruct blood flow to a sufficient degree to cause tissue necrosis. The patient can feel focal, sharp, pleuritic pain and exhibit a splinting response to breathing. Over several days, the infarcted segment becomes consolidated on chest radiography and exudes a pleural effusion, manifesting an intense underlying inflammatory process.\(^{21}\) The exact physiology of this process is unknown, but probably results in part from the consequences of chemokine production and hyperinflammation stimulated by normoxic ischemia.\(^{22}\) Chest pain from noninfarcting PE can be highly
variable and vague. About 30% of patients with definite PE have no perception of chest pain.

In contrast, if asked in a detailed and structured way, about 90% of patients with noninfarcting emboli admit to the sensation of dyspnea. The dyspnea may be constant and oppressive or may be intermittent and perceived only with exertion, possibly due to an exercise-induced increase in pulmonary vascular resistance. Rest dyspnea seems to be the clinical manifestation of distorted and irregular blood flow within the lung, referred to as ventilation-perfusion inequality. With each breath, a patient with PE wastes ventilation because of increased alveolar dead space (alveoli that are ventilated but not perfused). A lodged clot can redistribute blood flow to areas of the lung with already high perfusion relative to ventilation and as such cause more blue blood to pass through the lung without being fully oxygenated. This venous admixture is probably the primary cause of hypoxemia with PE and the increased alveolar-arterial oxygen difference (the A-a gradient).

About 15% of patients with PE have a normal A-a gradient of oxygen (with normal defined as age in years/4 + 4), however, and the A-a gradient is abnormally high in most patients who are evaluated for PE, but ultimately found to not have PE. In a multicenter registry of 348 patients with PE, 37 (10.6%) had a pulse oximetry reading of 100% at the time of arrival to the ED, while breathing room air. Although its shortcomings as a single diagnostic step, the presence of hypoxemia (pulse oximetry <95%, breathing room air) that cannot be explained by a known disease process definitely increases the probability of PE. Conversely, a normal oxygen saturation can be used only when considered together with multiple other clinical features and should not alone or independently be used to support a decision to forego further testing for PE (Box 86-2). Additionally, when PE is diagnosed, the severity of hypoxemia represents a powerful independent predictor of patient outcome.

PE also causes highly variable hemodynamic effects. In the ED, about half of all patients with PE have a heart rate greater than 100 beats per minute. Tachycardia from PE probably results from impaired left ventricular filling, leading to a pathophysiologic process that parallels that of hemorrhagic shock (see Chapter 4). When PE obstructs more than 50% of the vasculature, it usually causes an acute increase in right ventricular pressure. In contrast to the left ventricle, the right ventricle does not show an elastic response to acutely increased afterload; it quickly dilates, showing echocardiographic hypokinesis early in the course. In about 40% of cases, the right ventricular damage persists for at least 6 months and probably longer. Arterial hypotension represents an ominous hemodynamic consequence of PE; it occurs in only about 10% of patients, but signifies a fourfold increase in risk of death compared with normotensive patients. In its most extreme form, PE can obstruct the right ventricular outflow entirely, either by casting the entire pulmonary vascular tree (Fig. 86-2) or by acutely occluding the main pulmonary artery. Pulses electric activity (PEA) is the most common electrocardiogram (ECG) result from obstructive PE. The survival rate from cardiac arrest from PE is abysmally low, even if the arrest is witnessed and heroic treatment is initiated.

**Clinical Presentation**

Table 86-2 presents a listing of factors that significantly increase the probability of PE in a population of ED patients. As is the case for cardiac risk factors in the evaluation of acute chest pain, variables that increase the probability of PE in epidemiologic studies are not always useful for individual ED patients with signs and symptoms suggesting PE. For example, it is probably true from an epidemiologic standpoint that people who smoke are at a significantly higher risk for venous clots than are people who do not smoke. In the ED, however, the categorical presence of smoking in a given patient does not seem to increase that person’s risk for PE over that of a nonsmoker with an otherwise identical clinical presentation. It is possible that smokers are simply more likely to have other lung problems that manifest a clinical presentation similar to PE.

As many as 50% of patients diagnosed with PE have no apparent clinical risk factors for VTE. As such, some have postulated that these “idiopathic” PE might be associated with an increased frequency of thrombophilia-related genetic mutations that could be identified by laboratory investigation. However, a case-control study of 49 patients with idiopathic PE demonstrated no difference in the frequency of the thrombophilia genetic variants factor V Leiden G1691A or prothrombin G20210A compared with controls.

Virtually any ED visit related to weakness, shortness of breath, dizziness or syncope, pain, extremity discomfort, or nonspecific malaise or functional deterioration could represent PE. A patient with PE typically presents with 2 to 3 days of shortness of breath, now worsened enough to seek care. The chest pain usually is vaguely described. A few patients have focal pleuritic chest pain, but many say nonspecifically that their chest hurts with breathing, usually on the lateral aspects. Purely substernal chest pain is a rare presentation for PE and in general suggests a cardiac or other origin. Although a sudden onset of the symptoms might prompt more serious consider-
ation of PE as the cause, many physicians use the inverse logic that if the symptoms did not start suddenly, this somehow reduces the probability of PE to a level that justifies no further workup. This perception is incorrect because less than half of outpatients with PE describe either their dyspnea or chest pain sensation as being of “sudden onset.” When the antemortem histories of patients who die suddenly and unexpectedly from PE are reconstructed by interviewing family and examining medical records, most have complained of nagging symptoms for weeks before collapse, and 40% already had seen a physician for care.30

PE with lung infarction can present with a clinical picture that is similar to lobar pneumonia, including focal chest pain, fever, and unilateral rales on auscultation. However, a temperature greater than 103°F suggests infection rather than infarction. An occasional clue to pulmonary infarction is the onset of pain and red-blood hemoptysis on the same day, whereas lobar pneumonia usually presents with productive cough for a few days followed by rust-tined sputum.

The physical examination can sometimes provide specific information about the presence of PE, including unilateral leg asymmetry, suggesting presence of DVT. Jugular venous distention in a patient with severe dyspnea and clear lung fields on auscultation suggests pure right heart failure. The presence of wheezing suggests bronchospasm, which is not common in PE and makes the diagnosis less likely (but does not exclude it). Bilateral rales suggest the diagnosis of left ventricular failure, although localized rales often are heard over infarcted lung tissue. Astute clinicians may hear an accentuated pulmonary component of the second heart sound, or a right ventricular S3 sound.

Diagnosis

Chest radiography seldom provides specific information, but it is useful to suggest alternative diagnoses, such as pneumonia, congestive heart failure, or pneumothorax. Unilateral basilar atelectasis on chest x-ray increases the probability of PE.32 If symptoms have been present for 3 days or more, pulmonary infarction sometimes shows an apex-central, pleural-based, wedge-shaped area of infiltrate, producing the “Hampton’s hump” finding. Unilateral lung oligemia (Westermark’s sign) is a rare radiographic manifestation of a large PE.

Likewise, a 12-lead ECG provides more information about the presence of alternative diagnoses, such as pericarditis or cardiac ischemia, than the presence of PE. When PE causes ECG changes, this is usually a result of acute or subacute pulmonary hypertension. The most common effects of pulmonary hypertension on ECG are rapid heart rate, symmetrical T-wave inversion in the anterior leads (V1-V4), the McGinn-White SIQST3 pattern, and incomplete or complete right bundle branch block (Fig. 86-3).33

After the history and physical examination (with or without ECG and chest film data), emergency physicians are often compelled to evaluate for PE mainly because there is no other explanation for symptoms or signs consistent with PE. Symptoms include dyspnea or atypical chest pain, syncope, or seizure; signs include respiratory distress, altered consciousness, tachycardia, tachypnea, or hypoxemia. In the ED, unexplained symptoms and signs are as important as predictors of the presence of PE as the triad described by Virchow. Since as many as 50% of patients diagnosed with PE have no identifiable classic risk factors for thrombosis, the decision to pursue the diagnosis of PE seems to be a complex process, based on that particular patient’s presentation, which appropriately does not rely on the presence or absence of population risk factors.

In some cases, PE can be excluded with reasonable certainty based on data that are available at the bedside, gathered only by the medical history and physical examination. Multicenter studies of urban academic EDs have suggested that emergency physicians currently evaluate about 1 to 2% of all patients for PE.34 Each year, more than 16 million patients

DVT, deep vein thrombosis; PE, pulmonary embolism; V/Q, ventilation-perfusion ratio.
present to the ED with chest pain or dyspnea. Although numerous cases of PE are probably still missed, overtesting for PE can also be harmful. Specific risks include exposure to the ionizing radiation and IV contrast necessary for CTPA-CTV and the risk of unnecessary anticoagulation. The appropriate use of D-dimer testing decreases the need for imaging in all but patients at high risk.

A single CTPA examination imparts a relatively large radiation dose that probably increases the lifetime risk of cancer, especially in young women. Moreover, at least one third of all ED patients who receive one CTPA go on to have a second CTPA within 5 years. The IV contrast required for CTPA can cause anaphylactoid reactions, local tissue damage from high-volume contrast injection through a dislodged catheter, and contrast-induced nephropathy. The frequency of post-CTPA contrast nephropathy is probably between 4 and 12%.

Additionally, nonionic contrast material readily crosses the placenta, and the long-term effects of fetal contrast exposure are likewise unknown. Accordingly, there must be a rational, reproducible strategy to guide the decision-making and diagnostic processes. This strategy should begin with estimation of PTP. Methods for estimating PTP can be implicit (meaning the clinician's best guess) or explicit (meaning use of a scoring system or flow algorithm to categorize the probability). One approach to the workup for PE is to compare the PTP with the so-called test threshold for PE. The test threshold represents the point above which some type of workup should be initiated and below which the clinician can justify not starting the workup. For PE, the test threshold is approximately 2%. Patients with a PTP less than 2% are more likely to be harmed than benefited by a workup and vice versa for patients with a PTP greater than 2%.

The question becomes how to quantify the PTP accurately. One method is to use the implicit approach, in which the clinician draws from his or her own experience and surmises the probability of PE to be less than 2%. This method allows the inherent flexibility of human thought, but is subject to the conditions in the ED at the time (e.g., is one less likely to pursue a relatively low-likelihood diagnosis when the department is very busy), conditions of the clinician (e.g., fatigue, dysphoria, subjective feelings about the patient), and the availability of diagnostic studies (e.g., daytime versus nighttime, weekday versus weekend). In addition, there is the variability between clinicians who may not agree that a 19-year-old with cough and pleuritic chest pain, a normal chest radiograph, and no other risk factors has less than a 2% probability of PE.

Decision rules help to deal with these problems because they are structured and more transparent. Several rules have been derived and validated for the risk stratification of patients with possible PE; however, difficulty with spontaneous recall and a preference for gestalt reasoning by clinicians may effectively limit their use in clinical practice. Fortunately, clinical reasoning appears to be comparable to at least two of the validated decision rules. In a large single-center study of 2603 ED patients evaluated for PE, the treating clinician’s unstructured estimate of PTP was equivalent to that provided by the Wells score and the Charlotte rule. This finding was independent of training level, and interobserver agreement, measured in a subgroup of 154 patients, was good.

Although gestalt reasoning and clinical decision rules may provide adequate stratification to guide the workup (i.e., D-dimer vs. pulmonary vascular imaging), they have not been able to reproducibly identify the “very low risk” population whose PTP lies below the 2% test threshold. In one validation study, patients with the Wells score less than 2 had a 1.3% probability of PE, but this finding has not been repeated. To identify the very low risk group in whom PE could be safely excluded at the bedside with no diagnostic testing, the PE rule-out criteria (or PERC rule) were derived and prospectively validated in 8138 patients in 13 different hospitals across the United States and in New Zealand (see Box 86-2).

When the clinical suggestion for PE is low and each of the eight elements of the rule is satisfied, the PERC rule identifies a very low risk population among whom no patient has a PTP for PE of greater than 2%. In the large validation series, the rule excluded PE at the bedside in 20% of cases and yielded a false-negative rate of 1% (95% CI 0.6–1.6%). This finding supports a rational and reproducible method for avoiding unnecessary testing in a low-risk patient with a sign or symptom.
partially suggestive of PE. Patients with risk factors but without any symptoms or signs of PE (e.g., no chest pain, no shortness of breath, no dyspnea on exertion, normal or normalized vital signs, and no recent syncope) do not warrant workup for PE, unless there is some compelling clinical indication to the contrary.

PE also is less likely when some other disease process can explain the patient’s complaints and findings (e.g., asthma causing bronchospasm proven by a low peak expiratory flow rate, or findings of wheezing and prolonged expiration on auscultation) and the patient is otherwise not believed to be at high risk for PE. The finding that a confirmed alternative diagnosis reduces the probability of coincident PE has been shown in multiple settings.

Because of variation in patient populations and availability of clinical testing differences, there is no single algorithm for the evaluation of PE. The flow algorithms provided here are predicated on the following goals: (1) to identify as many ED patients as possible who have PE; (2) to avoid mislabeling (and administering anticoagulants to) patients who do not have PE; and (3) to use available resources efficiently and effectively (Fig. 86-4).

For a patient with a relatively concerning clinical picture (e.g., implicit suspicion or explicit score suggesting a PTP > 40%), it makes little sense to start with a screening strategy that applies to a low or moderate risk population, such as the D-dimer. Because the half-life of circulating D-dimer is less than 8 hours, the sensitivity of the D-dimer may decrease if the patient’s symptoms have been present for longer than 3 days. False-negative D-dimer measurements may also be seen with ingoing warfarin therapy and in the subset of patients with pulmonary infarction.

The post-test probability to safely exclude the diagnosis of PE must be equal to 1%, which is at least equivalent to that of a normal V/Q scan or a negative CTPA. This combination can be achieved by the combination of a PTP assessment less than 40% and a quantitative D-dimer concentration less than 500 ng/mL. When the PTP is relatively high, or the screening D-dimer is positive, pulmonary vascular imaging by CTPA or, less commonly, V/Q scanning is advised. Although CTPA is not perfect, it has multiple advantages over V/Q scanning and usually can be considered to definitively confirm or exclude the presence of PE.

The relative accuracy and precision of the V/Q scan were shown in the Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) study, which compared the results of V/Q scanning with the most accurate criterion standard test available at the time—formal pulmonary angiography (Table 86-1).

Adapted from the PIOPED Investigators: Value of the ventilation/perfusion scan in acute pulmonary embolism. JAMA 263:2753, 1990.

PE, pulmonary embolism; V/Q, ventilation-perfusion.

86-3. This multicenter study showed that a high-probability V/Q scan can be used to diagnose PE, and a normal V/Q scan (i.e., no perfusion defect) excludes the diagnosis of PE with an acceptable degree of certainty. A moderate probability or indeterminate scan requires additional formal pulmonary angiography or a CTPA. Even in patients with a low PTP, a low-probability V/Q scan usually indicates a need for additional testing, such as either CTPA or venous duplex ultrasonography of the legs. The latter should be repeated at least once, 2 to 7 days later, if negative at the initial presentation. In patients with a chest radiograph that shows airspace disease, the specificity of V/Q scanning can be expected to decrease, and the relative diagnostic utility of CTPA can be expected to increase.

Most academic centers now employ CTPA as the primary method of evaluating for PE. The PIOPED II study evaluated the test characteristics of CTPA for the diagnosis of PE in a prospective, multicenter study of 824 patients imaged primarily with four-row multidetector scanners. CTPA images were deemed adequate for interpretation in 773 (94%), and the sensitivity in these patients was 83% (95% CI 76–92%) with a specificity of 96% (95% CI 93–97%). Among the 737 (89%) with adequate CTV images, isolated DVT was diagnosed in an additional 14 patients (2%), effectively increasing the overall sensitivity for VTE to 90% (95% CI 84–93%) with a similar specificity of 95% (95% CI 92–96%).

When CTPA fails to identify PE in a situation of high clinical suspicion, it is often worth the time to investigate issues of image acquisition quality that can affect the certainty of the radiologist’s call on the presence or absence of PE. Good contrast enhancement of the pulmonary vasculature is probably the most important factor in determining the diagnostic quality of CTPA. Poor heart function complicates the timing of vascular opacification, but using bolus-timing software that is readily available on almost all modern CT scanners essentially should eliminate this factor. Obesity can compromise image quality and must be considered when determining the appropriate scanning parameters for each patient (i.e., milliampere-second [mAs], kilovoltage peak [kVp]). Motion artifact can severely degrade the quality of the images, as can severe intrinsic lung disease, such as stage 4 sarcoidosis or bulky carcinoma that can distort the vasculature and give false-positive appearances. Technical aspects that seem associated with better accuracy of the interpretation include specialty training of the reader, review of images in cine mode on a picture-archiving and communication system (PACS), a greater number of detectors on the scanner, and thinner collimation of the x-ray beam. There is no quantitative method to fold these findings into the computation of post-test probability except to say that if the scan quality was good, this should inspire more confidence in the radiologist’s interpretation. As with any imaging study, if CTPA quality was poor, and the results do not match the clinical picture, PE cannot be excluded or diagnosed with certainty, and more testing should be performed.

The importance of isolated subsegmental pulmonary embolus either missed or detected by CTPA can arise because of a radiologist’s statement that “subsegmental clot cannot be excluded by CTPA.” More recently, increased detection of isolated subsegmental filling defects occur with more thinly collimated images acquired with a higher number multidetector scanner. No firm evidence exists to guide these circumstances. When two radiologists independently evaluate CTPA, their agreement on the presence of isolated subsegmental filling defects is poor. The same lack of agreement in subsegmental clots holds for formal pulmonary angiography. Our opinion is that if the patient has no evidence of DVT, no signs of cardiopulmonary stress, and no ongoing major risk for thrombosis (e.g., active malignancy), isolated subsegmental findings or no findings together are a nonissue, and for either case, withholding anticoagulation would afford more benefit than harm. If a patient with negative CTPA has signs of pulmonary hypertension or hypoxemia without an apparent alternative cause, or has a known thrombophilia, further testing is advised. Subsequent testing after a negative CTPA is individualized by institution in consultation with radiology. Most commonly, if venous studies were not performed as part of the CTPA, duplex ultrasonography of both lower extremities should be undertaken. Positive sonographic evidence of DVT is considered confirmation of the presence of PE. A negative sonogram does not exclude the diagnosis, however, and should be repeated in 2 to 7 days.

CTPA can provide additional information to enhance its utility in the ED. First, without requiring any additional contrast injection, the legs can be scanned a few seconds later to provide a CTV, which can evaluate for DVT. Whether CT protocols should routinely include CTV remains an area of controversy. CTPA often provides information about alternative processes that might explain the patient’s symptoms (Box 86-5). Pneumonia is the most common alternative diagnosis found in ED patients. In about 10% of ED patients evaluated for PE, CT as a single test could (1) show absence of PE; (2) provide evidence of alternative disease, which can be used with other evidence to reduce the probability of PE to a reasonably low level to stop the workup; and (3) facilitate treatment for the alternative disease.

Management

Anticoagulation

Anticoagulation therapy is initiated when there is a high-probability V/Q scan, positive CTPA, or ultrasound evidence...
of DVT in a patient with a symptom or sign suggesting PE. Either unfractionated heparin (80 U/kg IV bolus, followed by 18 U/kg/hr IV infusion), fractionated heparin (e.g., enoxaparin, 1 mg/kg SC or IV every 12 hours), or the factor Xa inhibitor, fondaparinux (5–10 mg, depending on body mass) represents current standard treatment for most patients with PE. At present, no published evidence has proven the superiority of either form of heparin over the other. Both forms of heparin work equally well, and both are safe in the absence of contraindications to anticoagulation. Heparin provides several known benefits, including the reduction in formation of new clots (which can occur rapidly as clot volume increases exponentially with existing clot mass), and reduces the theoretical transient hypercoagulable effect of warfarin treatment, thought to be mediated by relative decrease in circulating protein C activity. Heparin also possesses anti-inflammatory properties that may help prevent pulmonary vasculitis associated with PE. As with DVT, administration of the first dose of warfarin in the ED can help shorten the time to therapeutic anticoagulation.

Heparin may be started before the results of imaging are known. In consideration of the risks and benefits of anticoagulation, empirical treatment seems to confer more benefit than harm when the PTP of PE exceeds 30%, the patient has no major contraindication to anticoagulation, and imaging would delay heparin initiation for greater than 24 hours.

For a patient diagnosed with PE in the presence of a major contraindication to anticoagulation, such as a recent cerebral hemorrhage or large cerebral infarction, the appropriate consultant should be contacted for urgent placement of an inferior vena cava filter. If vena cava interruption cannot be performed within 12 hours, one option is to perform a baseline head CT scan, then start an unfractionated heparin infusion at 18 U/kg/hr (without a bolus) and admit the patient to the intensive care unit for close neurologic monitoring and frequent partial thromboplastin time determinations. The rationale for using unfractionated heparin is that it can be reversed more reliably (by discontinuing the heparin drip and administering protamine, 1 mg/kg IV) than fractionated heparin. One small case series of four patients suggests that inhaled nitric oxide might be helpful for patients with severe PE and an absolute contraindication to anticoagulation, but this treatment has not been subjected to rigorous study.

Most patients with PE look and feel better the day after starting heparin anticoagulation, and more than half go on to a nearly full recovery of pre-PE health status. The in-hospital mortality rate of patients diagnosed with PE who remain hemodynamically stable while in the ED is about 10%. Another 10 to 20% complain of persistent dyspnea and exercise intolerance that permanently degrades their quality of life. Systolic hypotension (<90 mm Hg) represents a highly specific and moderately sensitive indicator of severe PE. In particular, persistent hypotension from PE increases the mortality rate dramatically. In the absence of hypotension, several parameters available at the bedside can help with prognosis. A heart rate that is persistently above the systolic blood pressure indicates more severe clot, as does a pulse oximetry reading less than 95%. Presence of prior congestive heart failure or advanced chronic obstructive pulmonary disease serves to magnify the severity of PE. Laboratory studies that portend a worse outcome include an elevated serum troponin measurement or an elevated brain natriuretic peptide or probrain natriuretic peptide concentration. Echocardiography demonstrating right ventricular hypokinesis or dilatation also increases the probability of death from PE. Table 86-4 summarizes the diagnostic accuracy of these predictors for the outcome of in-hospital death, shock, or respiratory failure. Consideration of these criteria, in combination with the patient’s hemodynamic status and comorbidities, may help guide the decision to place the patient in an ICU versus an intermediate or regular inpatient bed.

**Thrombolytic Therapy**

Thrombolytic therapy in PE is controversial. Administration of alteplase to patients with PE results in more rapid symptomatic improvement than standard antithrombotic therapy alone and causes more rapid normalization of right ventricular function. Alteplase also increases the risk of hemorrhage. It is not known how many patient lives would be saved, or definitively improved, by the addition of thrombolytic treatment to heparin therapy versus the number of patients who would experience a fatal or life-threatening bleeding event as a result of thrombolytic treatment. On balance, the benefit-risk analysis suggests that fibrinolysis is of greatest value in the subset of patients with proven PE who are likely to die, develop circulatory shock, or progress to respiratory failure in the first week. Massive PE is defined by hypotension as evidenced by a systolic blood pressure less than 90 mm Hg for more than 15 minutes. In patients with preexisting hypertension, the threshold is adjusted to less than 100 mm Hg or a greater than 60 mm Hg reduction in the baseline systolic blood pressure. In the absence of contraindications, patients with proven massive PE probably benefit from fibrinolysis. It remains controversial if or when, based solely on clinical

Patients considered for fibrinolysis should be carefully screened for contraindications and counseled on the incremental increase in bleeding risk above that of anticoagulation alone. For the feared complication of symptomatic intracranial hemorrhage, the risk is approximately 2% with fibrinolysis, which represents a small, but important increase over the 1 to 1.5% rate associated with heparin anticoagulation alone. If possible, consultation with cardiology or cardiac surgery should be obtained before administering fibrinolytic therapy for patients with PE who are not in extremis. The Food and Drug Administration–approved regimens for thrombolysis are shown in Table 86-5.

Tenecteplase is a recombinant plasminogen-activating enzyme with several pharmacologic properties that may favor its use for fibrinolysis of acute PE, despite its lack of FDA approval for this indication. Tenecteplase differs from alteplase with a longer half-life, resistance to plasminogen activator inhibitor-1, and increased fibrin specificity, which results in less fibrinogenolysis and less coagulopathy.

The clinical course of patients with obstructive PE can be unpredictable. Many patients with massive PE remain stable in the ED. Other patients “look fine” on arrival, but progressively deteriorate over hours as right ventricular function declines. Three percent of ED patients have no hypotension while in the ED, but experience cardiac arrest and die within 24 hours. A patient can be stable and then hypotensive within minutes because of the effect of variable right ventricular outflow obstruction from a large clot perched in the main pulmonary artery (Fig. 86-5). Additional mechanisms of rapid instability include new embolization of clot material, release of mediators of pulmonary vasoconstriction, sudden brady-asytolic arrhythmias, or respiratory failure. Clues to impending cardiopulmonary decompensation include worsening respiratory distress and worsening hypoxemia, a rising shock index (the heart rate divided by the systolic blood pressure), systolic arterial blood pressure less than 90 mm Hg, and syncope or a seizure-like convulsive episode while in the ED. A particularly ominous finding is the evolution on ECG from a narrow-complex tachycardia to an incomplete right bundle branch block to a complete right bundle branch block (Fig. 86-6). This progression (or regression) is evidence of life-threatening pulmonary hypertension and incipient cardiac arrest.

Clinical evidence of impending or actual respiratory failure indicates the need for prompt endotracheal intubation using standard rapid sequence intubation technique, preferably with either ketamine or etomidate for induction of anesthesia with neuromuscular blockade. Other induction agents that depress cardiac function or reduce preload may precipitate severe hypotension and as such they should be avoided or their dosage reduced. In the case of impending respiratory or cardiac arrest, fibrinolytic therapy should be strongly considered. For patients with known floating thrombi in the right heart or for patients with severe refractory hypotension, surgery is the most likely intervention to save the patient’s life. Surgical embolectomy requires extracorporeal cardiopulmonary bypass and an experienced cardiothoracic surgeon. Surgery may be the best option for patients who have severe PE with a contraindication to fibrinolysis; however, extracorporeal perfusion requires intensive heparin anticoagulation, and the patient’s mental status cannot be monitored during surgery—a key concern in patients with high risk of intracranial hemorrhage. Catheter thrombectomy also may be lifesaving, but requires that the patient be sent to the relatively uncontrolled environment of the interventional radiology suite.

PE can cause cardiac arrest. In the out-of-hospital setting, the arrest often appears to occur suddenly and unexpectedly. Most patients with incipiently fatal PE have overt respiratory distress, syncope or seizure-like activity, or a high heart rate relative to the systolic blood pressure before arrest. Compared with pure cardiac causes of arrest, a higher percentage of patients with arrest from PE have the initial arrest event witnessed, in particular by health care providers. First responders most commonly observe PEA as the initial cardiac arrest rhythm (>20 depolarizations per minute without palpable pulses). The mechanism for PEA seems to be pure right ventricular outflow obstruction complicated by impaired right ventricular contractility. Ultrasound performed during PEA...
arrest from PE usually shows weak cardiac contractions. The second most common rhythm after arrest from PE is asystole, or an agonal escape type rhythm with less than 20 complexes per minute. Mechanisms for brady-asystolic arrest include septal wall tension leading to ischemia or ischemic-equivalent effect on the atrioventricular node and infranodal conducting pathways.

Regardless of the initial rhythm, the development of pulselessness from PE imparts a mortality rate exceeding 70% in published studies. Numerous case reports have suggested heroic results from bolus administration of thrombolytic therapy to patients with cardiac arrest from PE. Notwithstanding these reports, the goal is to administer fibrinolytic therapy before cardiac arrest supervenes. The administration of fibrinolytic therapy does not absolutely preclude surgical intervention. Patients who have been treated with a fibrinolytic agent can undergo sternotomy or thoracotomy for embolectomy and survive without fatal hemorrhage. The decision to perform embolectomy ultimately resides with the cardiac surgeon.

Box 86-4 details questions that commonly arise regarding the diagnosis and treatment of PE in the ED.
1. I cannot get imaging at night. Is it reasonable to treat the patient with heparin until morning? The short answer to this question is yes, if the patient has no contraindications. Many smaller hospitals routinely employ this method, using a single dose of enoxaparin.

2. How do I manage the patient who is being treated for pulmonary embolism who returns to the ED for chest pain? If the patient has a therapeutic international normalized ratio (1.5–2.5) and returns with symptoms only (e.g., chest pain, dyspnea) and without syncpe, appears relatively comfortable, has normal vital signs, and has no new changes suggesting pulmonary hypertension on ECG (in particular, no STQ3T3 pattern and no T wave inversion in leads V1, through V3), follow-up imaging is probably not needed. Other causes of chest pain (especially acute coronary syndrome) must be considered. In the absence of an identified alternative diagnosis, symptomatic care with an anti-inflammatory agent is safe and reasonable therapy for the return complaint of chest pain. Persistent dyspnea at rest raises more concerns of unresolved or recurrent thrombosis with secondary effects, including bronchospasm or, worse, pulmonary vascular hyperplasia with pulmonary hypertension. Repeat pulmonary vascular imaging may provide evidence of an unresolved or new clot. More importantly, a transthoracic echocardiogram can disclose evidence of persistent right ventricular dysfunction and pulmonary hypertension. Symptomatic patients with unresolved filling defects and pulmonary hypertension can progress to chronic thromboembolic pulmonary hypertension. To prevent this decline, patients who return to the ED with persistent rest dyspnea and have unresolved filling defects and pulmonary hypertension should be admitted or referred to a program that offers the option of pulmonary thrombectomy.

3. How can I rule out pulmonary embolism in a pregnant patient without use of ionizing radiation? One clinical conundrum is the fact the pregnancy is accompanied by both an increased risk of PE and a predictable elevation in D-dimer, even in the absence of PE.70,71 Given that PE is the most common nontraumatic cause of death in pregnant women, clinicians are justified in adopting a liberal “rule-out PE” approach to all pregnant women with dyspnea.

Pulmonary V/Q scanning is safe in pregnancy and provides almost no risk to the fetus. A chest CT scan delivers about 250 mrad of energy, whereas the common threshold at which fetomaternal experts believe fetal teratogenicity becomes a concern is about 5 rad. The mother’s abdomen can be shielded, but the fetus will still receive a small fraction of the 250 mrad. There is a rapidly growing body of literature that suggests that exposure of the young brain to even small amounts of radiation can produce subtle cognitive deficits later in life, and at present the long-term consequences of CT scanning of pregnant patients are unknown. It seems logical to try to rule out PE with the D-dimer in pregnant patients; if D-dimer is negative in a patient believed to be at low pretest probability, this excludes the diagnosis. Moreover, coagulation systems are hyperactive in pregnancy, elevating the circulating D-dimer concentration. The D-dimer concentration increases linearly with duration of normal pregnancy, and about 75% of all pregnant patients evaluated for PE have a D-dimer concentration greater than the abnormal cutoff of 500 ng/mL.72 As an additional margin of safety, a negative venous ultrasound of the lower extremities excludes DVT and helps reduce the probability of PE by about half. V/Q scanning, if normal, excludes the diagnosis. A high-probability V/Q scan establishes the diagnosis, and heparin (which does not cross the placental barrier) can be initiated. If neither normal nor high probability, the V/Q scan is nondiagnostic, and further imaging (perhaps beginning with venous duplex ultrasound of the legs) is indicated.

4. How do I evaluate the patient with possible pulmonary embolism who is too obese to fit in a CT or V/Q scanner? Each CT scanner has a maximum patient weight that it will accommodate. When a patient’s weight exceeds the scanner limit, and a larger capacity scanner is not available, we recommend duplex venous ultrasonography of the lower extremities to rule out DVT. Although often technically suboptimal in a massively obese patient, venous ultrasound occasionally provides positive evidence of DVT, ostensibly clinching the diagnosis. Another option is to anticoagulate empirically based on a moderate-to-high pretest probability and a D-dimer concentration that exceeds 1000 ng/mL. The adequate regimen for anticoagulation is uncertain, but many experts recommend subcutaneous enoxaparin, 1 mg/kg of actual body weight up to a maximum of 200 µ/kg.

ESOPHAGEAL OBSTRUCTION

Perspective

Ingestion of foreign objects and esophageal food bolus impactions occur commonly. Although most pass spontaneously, approximately 10 to 20% require a nonoperative intervention and less than 1% require surgical removal. Death as a result of foreign body ingestion or impaction is rare. Most foreign body ingestions occur in children between the ages of 6 months and 6 years, with coins being the most commonly impacted objects. In adults, foreign body ingestion tends to occur in prisoners, alcoholics, psychiatric patients, and mentally impaired patients; many have a tendency for repetitive ingestion. Most adult impactions are due to pieces of food, particularly meat and bones. Patients with preexisting esophageal abnormalities are at greater risk for foreign body impaction. Denture wearers are also at increased risk because of impaired oral sensation.

Principles of Disease

The adult esophagus is approximately 25 to 30 cm in length. Superiorly, it begins in the hypopharynx as a transverse slit posterior to the larynx and approximately at the level of the cricoid cartilage. On either side of this cephalad slit are the piriform recesses, which are blind pouches that may occasionally harbor a foreign body. The esophagus is distensible; an adult can usually pass an object up to 20 mm in size without difficulty. Throughout its course, the esophagus has four natural areas of narrowing that may cause impaction of a foreign body: at the cricopharyngeus muscle (the upper esophageal sphincter), the aortic arch, the left mainstem bronchus, and the lower esophageal sphincter (LES) at the diaphragmatic hiatus. Most impactions occur in the mid to distal third of the esophagus. Large, proximal impactions can impinge on the trachea, leading to airway compromise presenting as choking, stridor, or cough.

The esophagus comprises two main bands of muscle: an inner circular layer and an outer longitudinal layer. The resting tone of these muscles causes the inner epithelium to fold in on itself, effectively obliterating the lumen. Elastic fibers enable the esophageal lumen to expand and allow passage of a food bolus. The upper one third of the esophagus, including the cricopharyngeus muscle, contains striated muscle to allow the voluntary initiation of swallowing. The middle portion of the esophagus is a mixture of skeletal and smooth muscle, and the distal third is composed only of smooth muscle.

Although it is relatively fixed at its origin, the esophagus becomes mobile as it traverses the mediastinum. Thus, it can be easily displaced by adjacent structures such as an enlarged left atrium or ventricle, a goiter, or a mediastinal tumor. Displacement of the esophagus may alter its shape enough to impede the passage of a food bolus or foreign body.

Clinical Features

Patients with an esophageal obstruction usually present with dysphagia (difficulty swallowing), odynophagia (painful swallowing), or chest pain. The obstruction may be partial or complete. The patient with complete obstruction is unable to swallow, is often drooling, and may be violently retching in an attempt to regurgitate the obstructing bolus. The patient may complain of pain from the neck to the substernal and epigastric area, although the perceived level of obstruction may not correlate with the actual site of the obstruction. Patients should be evaluated for the presence of stridor or signs of perforation or peritonitis.

A proximal obstruction may arise as a “café coronary,” characterized by sudden cyanosis and collapse caused by food (usually an unchewed piece of meat) lodging in the upper esophagus or oropharynx leading to airway obstruction. Similarly, “steakhouse syndrome” results when a large piece of food, usually improperly chewed, is swallowed and causes esophageal obstruction in the distal esophagus. The obstruction may be transient with spontaneous passage of the bolus and may be complete or partial. Intense discomfort develops shortly after swallowing a large piece of meat, and the patient is usually unable to swallow anything else. Ingestion of alcohol and absence of teeth are predisposing factors. Although obstruction may occur in a patient with a normal esophagus, abnormalities such as carcinoma, peptic stricture, or a Schatzki ring are identified in almost 90% of patients with an esophageal obstruction. Schatzki’s ring is a fibrous, diaphragm-like stricture near the gastroesophageal junction present in up to 15% of the population.

Aside from naturally occurring areas of anatomic narrowing, there are other pathologic causes of esophageal stenosis that may lead to symptoms of obstruction. Intrinsic causes of luminal narrowing include carcinoma and webs. An esophageal web is a thin structure composed of mucosa and submucosa. Although webs can occur in isolation, they are also seen in the Plummer-Vinson syndrome, which is characterized by anterior webs, dysphagia, iron deficiency anemia, cheilosis, spooning...
of the nails, glossitis, and thin friable mucosa in the mouth, pharynx, and upper esophagus. Most patients with this syndrome are women between 30 and 50 years of age. Patients usually present with dysphagia that is initially intermittent and worse with solids. If untreated, it may progress and become constant.

Extrinsic compression of the esophagus can occur in a variety of conditions. In the neck, thyroid enlargement from goiter or carcinoma may cause dysphagia. Symptoms may also be seen with a pharyngoesophageal or Zenker's diverticulum, a progressive outpouching of the pharyngeal mucosa as a result of increased pressure generated by failure of proper relaxation of the cricopharyngeus muscle. Noisy deglutition, dysphagia, foul breath, and a palpable compressible mass in the neck may be present. Laryngotracheal aspiration when the patient is supine results from the emptying of contents from the diverticulum.

Congenital anomalies of the aortic arch may cause dysphagia in both children and adults. In children, respiratory symptoms are also usually present and commonly predominate. In adults, an anomalous right subclavian artery is the most common vascular cause for dysphagia, which often does not become symptomatic until the fourth decade of life. The most common symptoms in adults are dyspnea on exertion and dysphagia. Vascular compression of the esophagus with dysphagia may also occur with aneurysms of the aortic arch and great vessels. Bronchogenic carcinoma can cause dysphagia by direct involvement of the esophagus or by compression with nodes.

Esophageal foreign bodies can occur atypically in small children or mentally impaired individuals. They may present with choking, refusing to eat, vomiting, blood-stained secretions, or respiratory distress.

**Diagnostic Strategies**

Plain radiographs of the neck should be obtained if a foreign body in the throat is suggested. Chest or abdominal radiographs may provide additional information. Coins are easily visualized. Disk batteries have a characteristic radiographic “double-density” appearance. Small bones or radiopaque objects may occasionally be visualized. Air in the tissues may be present if perforation has occurred. However, failure to demonstrate a foreign body on radiographs does not rule out its presence. Traditionally, contrast studies have been performed next (see later discussion); however, computed tomography (CT) has been used successfully to identify foreign bodies, particularly chicken and fish bones, and may be more sensitive than plain radiographs or barium examinations.2 Other nonorganic objects (e.g., Lego pieces) have also been successfully visualized with CT.3 CT scans have the additional value of visualizing changes in the surrounding tissues associated with perforation.

Hand-held metal detectors have been reported to be useful screening devices for locating metallic foreign bodies in children. They may also be of use in finding radiolucent metallic foreign bodies such as aluminum pull tabs. They do not, however, pinpoint the object.4

If available, endoscopy is helpful in diagnosing and treating esophageal foreign bodies. When endoscopy is unavailable, a radiographic contrast study may help in diagnosis. However, in addition to the risk of aspiration, the presence of contrast agents may make endoscopy more difficult. It is therefore advisable to consult with the endoscopist before performing any study in a patient with a suggested esophageal foreign body. If an esophageal perforation is possible a water-soluble contrast agent (e.g., diatrizoate meglumine [Gastrografin]) should be used first because barium induces an inflammatory response in tissues. Caution should be used, however, since Gastrografin can cause pneumonitis if aspirated. Failure to visualize a clinically suggested perforation warrants a repeated examination using barium as the contrast agent. Because barium may obscure subsequent endoscopic visualization, a minimal amount of thin barium should be used. The use of a swallowed barium-soaked cotton ball to identify the site of obstruction is not recommended because it adds an additional foreign body that then needs to be removed. Plain radiographs followed by contrast studies have false-negative rates of less than 1% and false-positive rates of less than 20%.5 Because of the risk of complications, a patient who may have ingested a sharp object should undergo evaluation up to and including endoscopy.

**Differential Considerations**

Esophageal foreign bodies must be distinguished from foreign bodies in the airway. This distinction can be especially difficult in small children. Radiographically, esophageal foreign bodies usually lie in the frontal plain and are best visualized in anteroposterior views. Tracheal foreign bodies tend to lie sagittally.

Patients with esophageal obstruction may present with retrosternal pain that can appear similar to that of an acute ischemic cardiac syndrome. The presence of odynophagia suggests an underlying mucosal lesion.

**Management**

Flexible endoscopy by an experienced endoscopist is the procedure of choice for removal of esophageal foreign bodies, as it is effective and relatively safe, with a complication rate of 8%.6 A recent retrospective study demonstrated that bougie-nage was a successful and safe method for coin removal in selected patients.7

**Upper Esophagus**

Oropharyngeal foreign bodies can usually be removed with a Kelly clamp or McGill forceps under direct visualization. Smooth upper esophageal foreign bodies can often be removed with a Foley catheter. This procedure requires an experienced technician, a cooperative patient, and fluoroscopic guidance. The patient is placed in a prone position, and the catheter is passed into the esophagus past the point of the foreign body impaction. The balloon is then inflated and the catheter withdrawn, pulling the foreign body with it. Controversy exists regarding the safety of this technique because there is no direct control of the foreign body.6 Prophylactic endotracheal intubation may be warranted to prevent the foreign body from entering the airway. When these maneuvers fail to dislodge the esophageal foreign body, consultation with a qualified endoscopist is indicated.

**Lower Esophagus**

Lower esophageal obstruction is usually the result of an impacted food bolus and can often be treated effectively in the emergency department (ED). Administration of 1 mg of glucagon intravenously (up to a total of 2 mg) may cause enough relaxation of the esophageal smooth muscle to allow passage of the bolus in approximately 50% of patients. Because glucagon affects smooth muscle only, it is only effective for impactions in the lower esophagus. Side effects of glucagon include vomiting, nausea, dizziness, and flushing. Glucagon should not be used in patients with sharp-edged, potentially
damaging foreign bodies or in patients with insulinoma, phaeochromocytoma, or Zollinger-Ellison syndrome.\textsuperscript{11}

Effervescent agents are sometimes effective in accelerating the passage of an obstructing food bolus. Although the mechanism of action is unclear, it is hypothesized that the carbon dioxide released from bubbles escaping the fluid acts to disrupt the impacted food bolus and to distend the distal esophagus. The administration of carbonated beverages (including soft drinks) results in the passage of the obstructing food bolus in 60 to 80% of patients treated.\textsuperscript{12,13} Studies combining the use of glucagon and an effervescent agent show rapid relief of symptoms in 65 to 75% of patients.\textsuperscript{14,15} It has been recommended that effervescent agents be avoided in cases of complete obstruction and cases in which an obstruction has been present for over 24 hours because of the theoretical potential of inducing perforation of a possibly ischemic distal esophagus. The use of meat tenderizer (papain) to soften a food bolus is not recommended. Although intact mucosa is resistant to papain’s effects, an inflamed mucosa becomes much more inflamed when exposed to this proteolytic enzyme, and esophageal digestion or perforation may occur.

Patients with sharp-edged, distal foreign bodies, those who have contraindications to use of the aforementioned agents, and those who do not respond to treatment should be evaluated with endoscopy. It is unclear whether CT or contrast radiographic studies performed to document the presence of obstruction are of any benefit in symptomatic patients.

Endoscopy should be performed immediately for patients experiencing significant distress and for children with impaction of an alkaline button battery. These batteries contain concentrated sodium or potassium hydroxide in addition to metals such as zinc, lithium, and mercury. Leakage of any of these can lead to systemic toxicity. Larger batteries have a greater risk of impaction and leakage. Batteries that pass into the stomach should be followed radiographically and clinically to ensure passage. Assistance with the management of a patient with button battery ingestion can be obtained through the National Button Battery Ingestion Hotline at (202) 625-3333 or at www.poison.org/prevent/battery.asp.

Urgent intervention is also indicated for sharp objects, disk batteries, coins in the proximal esophagus, and impactions that impair the handling of secretions. It is unclear whether patients with mild to moderate symptoms of esophageal obstruction from a suspected food bolus require immediate endoscopy. In such cases, some experts believe that emergent intervention is unnecessary if the patient is still able to handle secretions because the bolus often passes on its own. Others believe that the softened bolus makes endoscopic removal more difficult and predisposes to complications. Any object remaining in the esophagus for more than 24 hours carries a higher risk of complications, including perforation, aortoenteric fistula, tracheoesophageal fistula, or abscess. These complications may occur up to years after the ingestion. Most experts advocate follow-up endoscopic evaluation in all cases after an esophageal obstruction to rule out underlying pathologic conditions.

Stomach

Certain foreign bodies that pass into the stomach still require endoscopic retrieval. Objects longer than 5 cm or wider than 2.5 cm in diameter (e.g., toothbrushes, spoons) rarely pass the stomach. All sharp and pointed foreign bodies (e.g., toothpicks, bones) should be removed before they pass into the stomach because 15 to 35% may cause intestinal perforation. Smaller objects that pass into the stomach can be followed with stool inspections and with serial radiographs if necessary to confirm passage. Surgical removal should be considered for objects that remain in the stomach for more than 3 to 4 weeks or that remain in the same intestinal location for more than 1 week.\textsuperscript{16}

ESOPHAGEAL PERFORATION

Perspective

Esophageal perforation is a potentially life-threatening condition that must be identified and treated early to minimize morbidity and mortality. Although first reported by Boerhaave in the early 1700s as a result of forceful vomiting, it can also result from any Valsalva-like maneuver, including childbirth, cough, or heavy lifting. With its increased use over the past two decades, endoscopy has become the most common cause of esophageal perforation. Spontaneous perforation accounts for a minority of cases. Perforation has also been reported as a complication of both nasogastric tube placement and endotracheal intubation, including the use of the esophagotracheal Combitube.\textsuperscript{17,18} Other causes of perforation include foreign body ingestion, caustic substance ingestion, severe esophagitis, carcinoma, and direct injury related to blunt or penetrating trauma.

Principles of Disease

More than 90% of spontaneous esophageal ruptures occur in the distal esophagus. In contrast, rupture resulting from blunt trauma to the neck or thorax usually occurs in the proximal and middle third of the esophagus. Most iatrogenic injuries occur at the pharyngoesophageal junction because the wall in this area is thin and there is no serosal layer to reinforce it, and force is frequently used to past the tube beyond the level of the cricopharyngeus. Another site of frequent iatrogenic injury is the esophagogastric junction. In this area, the esophagus curves anteriorly and to the left as it enters the abdomen, and an endoscope has a greater likelihood of perforating the posterior wall. This usually occurs during therapeutic dilatation for strictures or achalasia. Other factors predisposing to iatrogenic perforation include anterior cervical osteophytes, Zenker’s diverticulum, esophageal strictures, and malignancies.

Perforation has been reported as a complication of most endoscopic procedures, including transesophageal echocardiography, sclerotherapy, or placement of a Sengstaken-Blakemore tube. When a perforation occurs, saliva and gastric contents can enter the mediastinum. Rapid spread of an infectious or inflammatory response to the surrounding tissues and organs occurs because of the thinness of the esophageal wall. Changes in intrathoracic pressure during respiration draw contaminants deeper into the mediastinum. The presence of gastric enzymes and other foreign material in the mediastinum induces an intense inflammatory response that may result in enough fluid buildup to displace adjacent structures.

Clinical Features

Clinical presentations vary and can depend on the cause, location, size, degree of contamination, and site of injury.\textsuperscript{19} Signs and symptoms can therefore be vague and nonspecific. Patients with an upper esophageal perforation usually present with neck or chest pain, dysphagia, respiratory distress, and fever. Odynophagia, nausea, vomiting, hoarseness, or aphonia may also result.

Patients with perforation of the lower esophagus may present with abdominal pain, pneumothorax, hydro pneumothorax, and pneumomediastinum. The pain often radiates into the back, to the left side of the chest, and to the left or both shoul-
Most patients have mediastinal or cervical emphysema, which may be noted by palpation or by a “crunching” sound heard during auscultation (Hamman’s sign). Abdominal examination may reveal epigastric or generalized abdominal tenderness, often with guarding and involuntary rigidity. Patients with severe mediastinitis may present in fulminant shock.

Pain, fever, dyspnea, or crepitus following esophageal instrumentation should be considered an indication of perforation until proved otherwise. Symptoms related to iatrogenic perforation may not appear until several hours after the procedure.

**Diagnostic Strategies**

Radiographic studies are used to establish the diagnosis of an esophageal perforation. A chest and an upright abdominal radiograph are usually obtained first; soft-tissue neck radiographs should be considered if a proximal perforation is suggested. Radiographic abnormalities may be detected in up to 90% of patients with esophageal perforation and include subcutaneous emphysema, pneumomediastinum, mediastinal widening, pleural effusion, or pulmonary infiltrate.21 Radiographic changes may not be present in the first few hours after the perforation.

Patients with possible perforation should have contrast radiographic studies performed. Controversy exists regarding the contrast agent of choice. Barium sulfate is superior in identifying small perforations; however, it may incite an inflammatory response in tissues. For this reason, some experts advocate the use of water-soluble agents (e.g., Gastrografin). However, the water-soluble agents are less dense and may not demonstrate the abnormality. Additionally, pneumonitis may result if these agents are aspirated. A prudent approach would be to attempt the study using a water-soluble agent first in patients who are not at risk for aspiration. If a clinically suggested perforation is not identified, the examination should be repeated using barium.

CT of the chest may be considered if a contrast study does not demonstrate a clinically suggested perforation. It can also be used in patients who cannot complete an esophagram. Findings such as mediastinal air, extraluminal contrast material, or fluid collections or abscesses adjacent to the esophagus confirm a perforation. These can be found after the initial perforation has healed. CT also allows evaluation of other adjacent areas that may suggest an alternative diagnosis. Endoscopy may be useful, especially in cases of trauma; however, small perforations may be difficult or impossible to visualize. Laboratory studies are not usually helpful soon after a perforation, although an elevated white blood count may be noted.

**Differential Considerations**

Misdiagnosis occurs in more than half of patients with esophageal perforation or rupture because the differential diagnosis includes the numerous causes of chest and abdominal pain, including pulmonary embolism, acute myocardial infarction, aortic dissection, perforated ulcer, pneumothorax, lung abscess, pericarditis, or pancreatitis. Esophageal perforations must be diagnosed as soon as possible because the morbidity and mortality associated with unrecognized perforations increases with time.

**Management**

Certain patients with esophageal perforation require rapid treatment. These include patients with Boerhaave’s syndrome; clinically unstable patients; and those with perforations that contaminate the mediastinum or pleura, intra-abdominal perforations, and perforations with an associated pneumothorax.22 Broad-spectrum intravenous (IV) antibiotics should be initiated early. The combination of a second-generation cephalosporin and an aminoglycoside usually provides adequate coverage. Patients should be kept with nothing by mouth (NPO), and a nasogastric tube should be considered to eliminate oral and gastric secretions. Early surgical consultation is warranted.

There is growing evidence that some iatrogenic perforations in certain patients at low risk can be managed conservatively with close observation. These include clinically stable patients, (minimal symptoms and fever with no clinical signs of shock), those whose perforation is contained, and those who present a long time after their procedure and have demonstrated no ill effects. They should be kept NPO and treated with broad-spectrum antibiotics and parenteral nutrition. These patients require diligent observation and assessment for failure of nonoperative therapy. Although not yet widely accepted, there is growing evidence for a role for endoscopic repair in selected patients.23

---

**ESOPHAGITIS**

**Perspective**

Esophagitis is defined as inflammation of the esophagus. The most common cause of esophagitis is gastroesophageal reflux disease (GERD). Other important causes include infectious esophagitis, pill esophagitis, and injuries from the effects of caustic ingestion, radiation, or sclerotherapy. Additionally, eosinophilic esophagitis, an new disease entity, is being diagnosed with increasing frequency.

**Principles of Disease**

**Infectious Esophagitis**

Esophageal infections in the immunocompetent host are relatively rare. If they do occur in healthy patients, there is usually an underlying esophageal abnormality or local area of immune compromise, as might occur with the use of inhaled steroids. Iatrogenic alterations in host defenses through the use of immunosuppressive agents, potent chemotherapeutic agents, and broad-spectrum antibiotics can predispose an individual to the development of esophageal infection. The spread of the human immunodeficiency virus (HIV) has also led to an increase in esophageal infections, although the epidemiology has been changing as more effective antiretroviral agents have become available. In addition to iatrogenic immunosuppression, diseases that weaken immunologic defenses in otherwise normal hosts can predispose the esophagus to infections. These conditions include diabetes mellitus, alcoholism, underlying malignancy, use of corticosteroids, and advanced age. Changes that occur in the mucosal barrier of the esophagus as a result of these conditions lead to an increased susceptibility to infection. The Candida species (primarily Candida albicans) are the most common esophageal pathogens.

As empirical antifungal prophylaxis in immunosuppressive states has become more common, viral esophagitis has become more prominent. Herpes simplex 1 and cytomegalovirus are the most common viral pathogens. Human papillomavirus has been implicated as well. Bacteria, mycobacteria, other fungi, and parasitic organisms such as Trypanosoma cruzi, Cryptosporidium, and Pneumocystis are uncommon causes of infectious esophagitis and are usually diagnosed by culture or biopsy.
Pill Esophagitis

Pill esophagitis is estimated to occur in approximately 10,000 people per year in the United States. However, because most cases are unrecognized and therefore unreported, the true incidence is unknown. The condition results when a pill or capsule fails to pass into the stomach and remains in contact with the esophageal mucosa for a prolonged period. The contents can become exposed, resulting in esophageal inflammation and injury. Pill esophagitis has been reported in all age groups. Predisposing factors include advanced age, decreased esophageal motility, and extrinsic compression. Large pills are more likely to be retained, as are those coated with gelatin. Pills can stick to a normal esophagus, especially when taken without water or while in the supine position. Any area of the esophagus can be affected, although sites of natural compression may be more susceptible. Sustained-release compounds may be more damaging than standard preparations. Injury can range from minor irritation to frank ulceration, hemorrhage, and ultimately stricture formation. Some of the more common offending medications include antibiotics (especially the tetracycline family) and antivirals, aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs), potassium chloride, quinidine, ferrous sulfate, alpenrolol, alendronate, and pamidronate.

Eosinophilic Esophagitis

Eosinophilic esophagitis was first described in 1978 and is defined by the presence of eosinophils within the esophageal mucosa or deeper tissues. Initially thought to be a disease of children, it is being diagnosed in adults with increasing frequency. Although usually seen in patients with GERD, it has been identified as a cause of heartburn or dysphagia that is unresponsive to standard GERD treatment. The cause is unknown, although there is an association with allergies, especially in the younger age group.

Caustic and Radiation-Induced Esophagitis

Esophagitis from caustic substance ingestion occurs most commonly in children, although adults may ingest a caustic substance in a suicide attempt. Strongly acidic or alkaline substances are the offending agents. The degree of injury depends on the concentration of the substance, the volume ingested, and the time in contact with tissue. Strong acids produce coagulation necrosis, which results in eschar formation that usually limits the damage. In contrast, alkali produces liquefaction necrosis, which continues to cause injury as long as the substance or its active breakdown products are in contact with tissue.

Patients undergoing radiation treatment for underlying malignancy may develop esophagitis. The degree of injury is related to the total dosage of radiation received. The mucosa becomes inflamed and friable. Agents used during sclerotherapy can also cause esophagitis.

Clinical Features

Esophagitis, regardless of cause, most commonly arises with dysphagia or odynophagia. Chest pain is frequently present and esophageal bleeding, ranging from localized oozing as a result of inflammation to frank hemorrhage, can occur. Ulceration and perforation can result in mediastinitis.

Infectious Esophagitis

Most commonly, infectious esophagitis causes severe odynophagia. Dysphagia of both solids and liquids may be present. Pain may be so severe that the patient refuses to eat or drink. Chest pain may also be present and may be described as acute in onset, constant, and not affected by antacid therapy. Heartburn (a burning sensation that begins in the subxiphoid area and radiates toward the neck) and nausea may be presenting symptoms. Some immunocompromised patients may have fever or bleeding without dysphagia or odynophagia.

Pill Esophagitis

Patients with pill esophagitis present with odynophagia. Most patients have no prior history of esophageal disease and present with sudden onset of pain worsened by swallowing. Dysphagia may be present. Although some patients may complain that a pill has become “stuck,” the history of pill ingestion may be difficult to obtain because symptoms may begin hours after the offending pill is taken. Atypical presentations include a burning type of pain suggesting GERD as the cause.

Eosinophilic Esophagitis

Patients usually present with dysphagia, food impaction, or heartburn. Esophageal dysmotility may also result. The diagnosis is made by biopsy during endoscopy.

Caustic and Radiation-Induced Esophagitis

Patients with caustic injuries may present with pain in the mouth, chest, or epigastrium. Dysphagia and vomiting may be present. Patients may be drooling. Airway compromise may be present because of direct tissue injury or resulting edema. Later, perforation may occur, and strictures are a common long-term complication. Radiation-induced esophagitis usually causes odynophagia and dysphagia. Strictures may ultimately develop.

Diagnostic Strategies

Endoscopy is the best method of diagnosing both pill-induced and infectious esophagitis. With infectious esophagitis, direct visualization may reveal characteristic signs of infection, such as white plaques of Candida or herpetic vesicles. Definitive diagnosis can be made through brushings and biopsies. Radiographic studies are usually not helpful because the findings are nonspecific. A strong clinical suggestion is necessary to diagnose pill esophagitis. The other causes of esophagitis are usually clinically apparent.

Differential Considerations

Other causes of esophageal pain include GERD, esophageal motility disorder, foreign body, and perforation. Chest pain may also be a component, and therefore an acute coronary syndrome must be considered. Esophageal pain is more likely to be positional and related to swallowing.

Management

Infectious Esophagitis

For infectious esophagitis, therapy should be directed at the causative organism. Patients with normal immune systems and mild cases of candidal esophagitis can be treated with clotrimazole troches (10 mg dissolved in the mouth five times a day for 1 week) or nystatin (1–3 million units PO four to five times per day for 2 weeks). Some of the newer antifungal agents, such as fluconazole (200 mg PO daily for 3–4 weeks), ketocon-
azole (300–400 mg PO daily for 3–4 weeks), or itraconazole (100–200 mg PO daily for 3–4 weeks), may be used for more advanced infections in immunocompromised patients. They may also be used for a shorter duration in patients with less severe infections.

Initial treatment for herpes simplex esophagitis includes antivirals, such as acyclovir (400 mg PO five times per day for 7–14 days or 5–10 mg/kg IV every 8 hours for 7–14 days), famciclovir (500 mg PO three times a day for 7–14 days), or valacyclovir (500 mg PO twice a day for 7–14 days). For cytomegalovirus, initial treatment can begin with ganciclovir (5 mg/kg IV every 12 hours for 2–3 weeks) or foscarnet (60 mg/kg IV every 8 hours or 90 mg/kg IV every 12 hours for 2–3 weeks).26

If the causative organism cannot be adequately identified or if the patient is severely debilitated, admission to the hospital may be required. Patients discharged from the ED should receive appropriate follow-up with the relevant department (e.g., gastroenterology, infectious disease). In addition to therapy directed at the infecting organism, treatment with antacids, topical anesthetics, or sucralfate may provide symptomatic relief.

Pill Esophagitis

If a patient with suggested pill esophagitis has persistent symptoms, endoscopy may be necessary. It also helps to determine alternative causes. No data exist supporting any specific treatment, although, intuitively, antacid medication may prevent further erosion of damaged mucosa. Symptoms may take up to 6 weeks to resolve.

The best treatment for pill esophagitis is prevention. Patients should be instructed to drink at least 4 ounces of liquid with any pill. All medications should be taken when the patient is in an upright position, and the patient should remain upright for several minutes after medication ingestion. Patients with underlying esophageal abnormalities or those who are bedridden should avoid the use of pills whenever practical.

Eosinophilic Esophagitis

These patients usually present after standard antireflux measures have failed or if they develop a food impaction. The treating physician should consider the possibility of food impaction, ensure that appropriate antacid therapy is employed, and refer the patient to a gastroenterologist for further treatment. Although consensus has not yet been reached regarding an optimal treatment regimen, success has been reported with the use of topical (e.g., swallowed) corticosteroids.

Caustic and Radiation-Induced Esophagitis

Management of caustic injuries includes evaluation and management of possible airway injury, followed by assessment of the extent of esophageal involvement. Although the use of mild diluents like water or milk to limit the extent of chemical injury has been advocated by some authors, others warn against the possibility of inducing emesis, which reexposes the esophagus to the caustic substance. In general, it is probably best to avoid having patients ingest anything by mouth while undergoing evaluation. Likewise, gastric lavage and the administration of charcoal are not indicated. Symptomatic patients should be admitted to a monitored setting for observation, further evaluation with endoscopy, and treatment of complications, such as perforation. Asymptomatic patients who give a reliable history of a low-volume, accidental ingestion of a low concentration of an acidic or alkaline substance can be discharged after a period of observation and followed as outpatients.

Treatment of radiation esophagitis is supportive. Patients who cannot eat or drink because of radiation injury to the esophagus should be admitted for IV fluid therapy.

GASTROESOPHAGEAL REFUX DISEASE

Perspective

Asymptomatic reflux of gastric contents from the stomach into the esophagus occurs in most people several times a day as a normal physiologic phenomenon. GERD occurs when reflux becomes symptomatic or causes histopathologic alterations in the upper gastrointestinal (GI) or respiratory tracts. In the United States, symptomatic reflux in the form of heartburn occurs daily in 7% of adults, weekly in 14%, and monthly in 40%.

Principles of Disease

Although the anatomic relationship between the cardia of the stomach and the left side of the esophagus prevents reflux of gastric contents into the esophagus, the major barrier to gastroesophageal reflux is the lower esophageal sphincter (LES). A defective LES is believed to be the primary mechanism in pathologic reflux by allowing a larger volume of refluxate to enter the esophagus.27 When reflux does occur, gravity, peristalsis, normal swallowing of saliva, and secretions from esophageal glands help clear refluxed gastric contents back into the stomach. Factors also operate at the mucosal level to minimize the damage caused by refluxate.

Other mechanisms that may contribute to GERD include esophageal motility abnormalities, increased intragastric pressure (e.g., obesity, pregnancy), acid hypersecretion, gastric outlet obstruction, and conditions that cause delayed gastric emptying (e.g., gastroparesis, neuromuscular disease). The presence of a hiatal hernia (the prolapse of a portion of the stomach through the diaphragmatic esophageal hiatus), formerly thought to be synonymous with GERD, may be a factor in the initiation of GERD pathogenesis by interfering with the function of the LES. However, hiatal hernia is thought to play a greater role in sustaining GERD, as one is found in approximately 90% of patients with severe GERD and its complications.26-29

Clinical Features

Symptoms

The most common manifestation of GERD is reflux esophagitis, of which the most common symptom is heartburn, defined as a burning sensation that begins in the subxiphoid area and radiates toward the neck. Reflux may also cause a dull discomfort, localized pressure, or severe squeezing pain across the middle of the chest. This type of pain has been postulated to be a result of acid-induced esophageal spasm, but this is believed to be uncommon. The patient may appear comfortable or may have associated diaphoresis, pallor, nausea, and vomiting, leading to the consideration of an ischemic cardiac syndrome. A detailed history is often helpful in differentiating cardiac chest pain from reflux, although the distinction may not be possible in the ED.

Other symptoms of GERD include regurgitation (the spontaneous appearance of acid or bitter material in the mouth or pharynx) and water brash (a vagally mediated hypersalivation response that may produce as much as 10 mL of saliva in 1

Complications

Repetitive exposure to acid can lead to changes in the esophageal mucosa. Continued reflux can lead to thinning of the normal stratified squamous epithelial layer. With the development of esophagitis, an inflammatory response occurs within the mucosa and submucosa with infiltration of polymorphonuclear leukocytes. The inflammatory response is the result of chemical irritation of the esophageal mucosa from reflux of gastric acid, pepsin, and bile acids. Both acid and alkaline refluxes produce the same pathologic changes. Continued exposure can lead to further endoscopically visible changes of erosion, ulceration, and scarring. Ultimately, stricture formation may result. The most severe histologic consequence of GERD is replacement of the normal stratified squamous epithelium with metaplastic columnar epithelium in a condition known as Barrett’s metaplasia. Histologically, it is characterized by a villous architecture with goblet cells. There is a strong correlation between the development of Barrett’s metaplasia and adenocarcinoma of the esophagus.

Diagnostic Strategies

GERD is a common problem, and additional diagnostic testing in the ED is rarely necessary, assuming other more serious causes of the patient’s symptoms have been excluded. Patients with dysphagia, odynophagia, or bleeding should be referred for further study.

Differential Considerations

One should consider acute ischemic cardiac syndromes as a possible cause of chest pain in adults. Radiation of pain is an inconstant finding in both esophageal and cardiac chest pain. The pain seen with reflux may radiate into the neck, jaws, shoulders, back, arms, and abdomen. Radiation into the back is more often ascribed to the esophagus. Radiation of pain into one arm or into the neck or jaw is not helpful in distinguishing ischemic cardiac pain from esophageal pain. Radiation of pain into the abdomen is present approximately three times more often in reflux than in ischemic heart disease. Radiation into both arms is rarely seen in reflux, whereas it may be present in approximately one quarter of patients with ischemic heart disease. Precipitation of pain by exercise and relief by rest may occur in pain from reflux as well as in ischemic heart disease. Emotional precipitation of pain occurs in reflux, although it is also seen with coronary artery disease. The occurrence of reflux after meals is another important feature in the history. A feeling of fullness after meals occurs commonly in reflux and is helpful in differentiating it from coronary artery disease.

Relief of chest pain from reflux by antacids is a key point in the history; however, one should not place too much weight on this point as evidence against a cardiac etiology. The relief is often short-lived, and pain may recur in a short time. Esophageal pain may be brought on by swallowing. The physical examination in patients with esophageal reflux is not usually helpful in diagnosis. Thus, the history is by far the most valuable aid. It is important to maintain an acute awareness of the diverse presentations of ischemic heart disease and to be cautious in attributing chest pain to esophageal causes solely on the basis of historical elements. Other GI disorders such as gastritis, esophagitis, peptic ulcer disease, and biliary tract disease should be considered in the differential.

Management

Earlier treatment guidelines for GERD recommended lifestyle modification solely as an initial approach; however, this approach has been shown to have little therapeutic benefit without concomitant medical management. These recommendations are thought to decrease the number of reflux
episodes and facilitate the clearance of refluxate. Patients should be counseled to avoid the following: lying fully recumbent during sleep; eating before retiring; wearing tight garments; performing heavy physical exercise after meals; using anticholinergic drugs; consuming foods; or using agents that decrease LES tone, such as cigarettes and alcohol. Direct irritants to the esophagus such as coffee, citrus fruits, and tomato-based products should also be avoided. Overweight patients may experience relief with weight loss. Avoidance of fatty foods and consumption of smaller meals may also help alleviate symptoms. A recent review demonstrated that weight loss and bed elevation are the only recommendations that have evidence-based support.

The pharmacologic therapy of GERD includes agents that neutralize acids, decrease acid production, act on the LES or affect motility, and protect the mucosa. The most effective treatment for GERD is reduction of acid production. Many patients initially self-medicate with antacids or over-the-counter-strength H2 receptor antagonists or proton pump inhibitors (PPIs), both of which have been demonstrated to relieve and prevent symptoms. Recent studies show that PPIs are more effective than H2-blockers in eliminating symptoms and healing mucosal damage. However, H2-blockers are often effective in patients with mild to moderate GERD. These agents do not stop the reflux but rather reduce the potency of the refluxate. Choices of H2-blockers and PPIs are listed in Tables 87-1 and 87-2. All of these agents are now generally regarded as safe and effective.

Prokinetic agents treat GERD by increasing LES pressure. They may also be used for patients whose symptoms suggest a superimposed motility disturbance (e.g., regurgitation, choking, abdominal distention). In addition to improving propulsive activity of the stomach and small and large intestine, the increase in esophageal peristalsis and LES tone make an effective therapy for reflux by improving the clearance of refluxate. Cisapride (Propulsid) was formerly used for this purpose but was withdrawn from the marketplace by the manufacturer because of adverse cardiac effects. Metoclopramide, a dopamine antagonist, may be used for these patients, but its efficacy has not been conclusively demonstrated and it has significant side effects, some of which are irreversible (e.g., tardive dyskinesia). Baclofen has been used with some success in selected patients. Candidates for this type of therapy are probably best chosen by a gastroenterologist.

Another agent that may be of benefit in refractory cases of symptomatic esophageal reflux is sucralfate, the salt of aluminum hydroxide and sucrose octasulfate. It may have an advantage in that it also absorbs and inactivates bile salts. However, this indication for its use is not approved by the Food and Drug Administration.

Although the emergency physician can initiate antireflux therapy, the patient with clinically suggested reflux should be referred to a gastroenterologist to confirm the diagnosis and provide follow-up care. Further diagnostic evaluation, including esophageal pH monitoring, an upper GI radiographic series, esophageal manometry, or esophagoscopy may be necessary, especially for patients who fail to respond to all of the preceding measures. Patients whose condition is medically unresponsive may be candidates for antireflux surgery. Endoscopic therapies such as endoscopic sewing, polymer injection, and radiofrequency application to the lower esophageal sphincter are currently being investigated.

### GASTRITIS

#### Perspective

Strictly speaking, gastritis is a histologic diagnosis denoting inflammation of the gastric mucosa. Hence, the diagnosis of gastritis can be made only by endoscopy and biopsy. However, it is common practice for clinicians to use the term gastritis to refer to symptoms of dyspepsia. To confuse the picture further, gastroenterologists frequently use the term to refer to the endoscopic finding of an edematous, friable mucosa. However, without accompanying inflammation, this is more appropriately termed gastropathy rather than gastritis. Controversy exists regarding how best to classify the entities that cause gastritis or gastropathy. This section considers gastritis and gastropathy together as one entity because the distinction makes little difference in the ED setting. Regardless of the cause, up to 50% of the population have endoscopic evidence of gastritis or gastropathy by age 50.

#### Principles of Disease

The most common cause of gastritis is infection with Helicobacter pylori. Although most patients are asymptomatic at the time of initial exposure, acute infection with H. pylori can cause severe gastritis and upper GI symptoms. Suppurative gastritis (also known as acute phlegmonous gastritis) can result from a bacterial infection of the stomach wall, usually from gram-positive cocci or gram-negative rods. Patients usually have an underlying mucosal abnormality such as cancer, ulcer, or preexisting gastritis. Less common infectious causes of gastritis include mycobacterial, viral, parasitic, and fungal organisms.

Gastritis can also result from exposure to drugs. Aspirin or other NSAIDs are the most common offending agents. Inflammation occurs as a result of prostaglandin inhibition both locally and systemically and is probably a precursor to gastric ulcer formation. Other drugs implicated in causing gastritis are
potassium preparations and iron supplements. Gastritis can result from both short- and long-term exposure to ethanol, although some authors feel that the long-term effects are more likely due to H. pylori rather than to the ethanol itself.

The presence of corrosive agents in the stomach can induce gastritis. Intrinsic substances such as bile or ingested substances such as acids, alkali, and corrosive agents can induce an inflammatory response and subsequent gastritis.

Any condition that causes hypovolemia or hypotension can lead to gastritis. Ulcer formation may ultimately result. This may be a major causative factor in the development of gastritis and upper GI bleeding in intensive care unit patients. Other causes of gastritis include radiation, autoimmune reactions, Crohn’s disease, and sarcoidosis. These disorders can be diagnosed only by biopsy.

Clinical Features

No particular symptoms are characteristic of gastritis. Acute gastritis may cause abdominal pain, nausea, and vomiting, although most patients are asymptomatic unless ulcers or other complications develop. By definition, it is not possible to diagnose gastritis or gastropathy on the basis of clinical features alone. However, a good clinical history such as recent NSAID use or alcohol ingestion in the setting of the foregoing symptoms supports a presumptive clinical diagnosis of gastritis.

Acute infection with H. pylori may cause epigastric abdominal pain, nausea, and vomiting. Systemic signs such as fever are usually absent. Symptoms may last days to weeks. If the infection goes untreated, chronic gastritis may result. Patients with phlegmonous gastritis usually appear toxic. Patients with gastritis as a result of decreased mucosal blood flow may present with symptoms of abdominal pain and upper GI bleeding in addition to those of their underlying disease. Complications of gastritis include perforation and gastric outlet obstruction.

Diagnostic Strategies

Because the presumptive diagnosis of gastritis is made empirically, no specific diagnostic tests are necessary. Ancillary tests should be ordered as clinically indicated to rule out other possible diagnoses or to assess for complications of gastritis, such as bleeding, obstruction, or perforation.

Differential Considerations

Before making the diagnosis of gastritis, other diseases that cause nausea, vomiting, and upper abdominal pain, such as pancreatitis, biliary tract disease, and small bowel obstruction, must be excluded. The possibility of an acute coronary syndrome should also be considered, particularly in elders.

Management

Therapy of presumptive gastritis should be directed toward treating the suggested underlying cause. Acid suppression may improve symptoms of dyspepsia in patients taking NSAIDs. Patients with persistent symptoms should be referred to a gastroenterologist for further diagnostic evaluation.

PEPTIC ULCER DISEASE

Perspective

Gastric and duodenal ulcers are usually grouped together as peptic ulcer disease (PUD) because of the similarity in their pathogenesis and treatment. Approximately 4 million people in the United States are affected by PUD each year.32 The annual cost to the health care system is estimated to be over $15 billion.32 PUD is now considered to have two main causes: H. pylori infection and NSAID use. Approximately 1% of PUD is caused by increased levels of circulating gastrin from gastrin-secreting tumors (Zollinger-Ellison syndrome). These patients have increased parietal cell mass and hypersecretion of acid leading to ulcer formation. A small minority of patients have no identifiable cause for their ulcers.

Principles of Disease

Histologically, the stomach is composed of different types of cells with varying secretory functions. Mucous cells secrete acidic mucus, parietal cells secrete hydrochloric acid and intrinsic factor, chief cells secrete pepsinogens, and enterochromaffin-like cells release substances such as histamine and gastrin. Acid secreted by the over 1 billion parietal cells can generate a hydrogen ion concentration gradient of greater than 1 million to 1 within the lumen of the stomach.

Many mechanisms exist to protect the gastric mucosa from the digestive effects of the hydrochloric acid, proteolytic enzymes, bile, and other injurious substances to which it is exposed. Normally, a gastric mucosal barrier to intraluminal gastric acid is present and prevents the back-diffusion of hydrogen ions from the gastric lumen. Sodium ions are barred from moving in the opposite direction. This ionic impermeability protects the gastric mucosa from damage in a hostile environment. Damage to the gastric mucosal barrier from any cause (Box 87-2) allows hydrogen ions and digestive enzymes to make contact with the gastric mucosa, leading to inflammation, bleeding, and potential ulceration.

The identification of H. pylori has proved to be a landmark discovery that has changed our understanding of PUD. H. pylori is an spiral, flagellated, gram-negative rod whose natural habitat is the human stomach between the epithelial cell surface and the overlying mucus. Infection with H. pylori is a primary risk factor for development of PUD. It is estimated that 70 to 80% of patients with duodenal ulcer and 60 to 70% of patients with gastric ulcer are infected with H. pylori. H. pylori is more prevalent in lower socioeconomic groups and is probably spread by the fecal-oral route, although oral-to-oral and iatrogenic transmissions have also been suggested. It is estimated that 30 to 40% of the U.S. population is infected with H. pylori. It is found in all age groups, although it is believed that infection is acquired during childhood. Its presence is believed to cause mucosal inflammation that disrupts the normal defense mechanisms and leads to ulceration. It also increases the risk of gastric carcinoma and, less often, lymphoma. Not all people infected with H. pylori develop PUD.

PUD also occurs in infants and children. Infants with PUD usually present with poor feeding, vomiting, or failure to thrive, but hematemesis may be the first sign. Toddlers and preschool children may have abdominal pain or vomiting and bleeding. Eighty percent of ulcers in this age group are stress ulcers. Older children and adolescents usually have primary PUD, with presentations similar to those of adults.

**Clinical Features**

**Presenting Symptoms**

Although 1 to 2% of patients with ulcers are asymptomatic, the most common symptom of PUD is abdominal pain. Classically, ulcer pain is described as nonradiating epigastric pain of a burning, gnawing, or “hunger-like” quality. However, patients may also describe pain in other areas of the abdomen, the chest, or the back; the pain may also be vague or crampy. It usually occurs 2 to 5 hours after a meal or at night. Pain that awakens a patient from sleep between midnight and 3 am is a classic indicator of ulcer disease, because in most people gastric acid output is highest at about 2 am. Ulcer pain is usually not present on awakening in the morning because gastric acid output is at its lowest at this time. Colicky pain is rarely gastric or duodenal in origin. Well-defined periods of exacerbation and remission are usually present with duodenal ulcer and aid in the diagnosis. A constant pain lasting from weeks to months is uncommonly caused by ulcer disease. Relief of pain after eating is another feature of gastric or duodenal ulcer. The pain from a duodenal ulcer is usually worse immediately preceding a meal, and the complex of pain-eating-relief is typical of duodenal ulcer.

Although some patients with ulcers may vomit, alternative diagnoses such as gastric volvulus, gastric outlet obstruction, small-bowel obstruction, pancreatitis, or biliary tract disease should be considered in patients who present with epigastric pain and vomiting. Relief of abdominal pain with antacids is an important aspect of the history. Antacids usually afford relief of pain in both PUD and gastritis. Ninety percent of patients with PUD have pain relief with antacids, and 75% with gastritis have relief. Patients with duodenal ulcer usually experience pain relief within 5 minutes after taking an antacid.

Physical findings in patients with PUD are usually minimal. Mild epigastric tenderness may be elicited. A positive stool guaiac test may be evidence of a bleeding ulcer, but other causes of occult bleeding must also be considered.

**Complications**

The most serious complications of PUD include hemorrhage, perforation, penetration, and gastric outlet obstruction. Hemorrhage is the most common complication, occurring in 15% of patients. Ulceration into an artery can lead to life-threatening hemorrhage. Older patients are at greater risk. Approximately 7% of patients experience perforation, which occurs when an ulcer erodes through the wall and leaks air and digestive contents into the peritoneal cavity. Penetration is pathologically similar to perforation, except that the ulcer erodes into another organ such as the liver (usually from a gastric ulcer) or the pancreas (usually from a duodenal ulcer) instead of into the peritoneal cavity. Gastric outlet obstruction occurs in 2% of ulcer patients as a result of edema and scarring near the gastroduodenal junction. Symptoms may manifest as gastroesophageal reflux, early satiety, weight loss, abdominal pain, and vomiting.

Pain patterns may be helpful in diagnosing some of the complications of PUD. Pain from a perforated duodenal ulcer is usually appreciated first in the epigastrium but becomes generalized within a short time. Vomiting is present in 50% of patients, and peritoneal findings usually result. Pneumoperitoneum commonly occurs after duodenal ulcer perforation, and the accumulated air under the diaphragm may cause referred pain to the shoulder. One or both shoulders may be involved, depending on the location of the free air.

A history of ulcer-like anterior abdominal pain that begins to radiate into the back suggests penetration of a duodenal ulcer. The pain is usually described as steady and is perceived at the level of the lower thoracic and upper lumbar vertebrae. Relief of the pain with antacids and food often vanishes, and the pain becomes refractory to treatment. Also, pain radiation may occur to the chest, right upper quadrant, and left upper quadrant in up to 20% of patients. The sudden onset of pain, especially if unrelated to eating, suggests either ulcer perforation or gastric volvulus.
Diagnostic Strategies

The initial diagnosis of PUD is usually made clinically. Upper endoscopy is the procedure of choice for confirming the diagnosis. Ancillary tests may be of benefit in evaluating possible complications of PUD in patients who present in distress. They may also be of benefit in providing indirect evidence of another disease. A complete blood count may diagnose anemia, and liver enzyme levels may help elucidate a hepatic or biliary tree etiology. Electrolytes may provide indirect evidence of disease, and assessment of amylase and lipase levels should be considered to rule out pancreatitis and may provide indirect evidence of a posterior penetrating ulcer.

Abdominal and chest radiographs should be ordered if obstruction, perforation, or penetration is suggested or if a pulmonary etiology is being considered, although negative radiographs do not definitively rule out these diagnoses. Electrocardiography should be performed in any patient thought to have a cardiac etiology for the pain. A pregnancy test should be performed on any woman of childbearing age.

As noted earlier, several methods exist for diagnosing infection with *H. pylori*, although at this time none is of practical application in the ED.

Differential Considerations

Fifty percent of patients with symptoms of dyspepsia have no identifiable cause. These patients are classified as having non-ulcer dyspepsia (NUD). The official criteria for diagnosing NUD are chronic recurrent upper abdominal pain or discomfort for a period of at least 1 month, with symptoms present more than 25% of the time, and no evidence of organic disease.²⁵

NUD may be caused by peptic ulcers that are not yet large enough to appear endoscopically. Gastritis related to hypersecretion of gastric acid, *H. pylori* infection, bile reflux, or viral infection may cause NUD, although these cases should be identifiable endoscopically or pathologically. Malabsorption of carbohydrates can arise as NUD in patients with lactase deficiency or in patients who consume large quantities of nonabsorbable sugars such as sorbitol, mannitol, and fructose. Intestinal parasites such as *Giardia intestinalis* or *Strongyloides stercoralis* may cause NUD, as can chronic pancreatitis. NUD may also be caused by gastric motility disorders, which have been reported in 25 to 60% of patients with NUD. Abnormalities in the biliary tract, such as increased resting pressure of the sphincter of Oddi, or incomplete relaxation of the sphincter on gallbladder contraction may lead to bile duct distention and pain.⁵⁶

Many other disorders can produce epigastric pain that mimics the pain of an ulcer. It can be difficult to distinguish between gastritis and PUD. The discomfort associated with gastritis is often mild to moderate in severity and described as a hot, burning pain or bloating. In particular, burning pain is twice as common in gastritis as in PUD. Esophageal disorders such as GERD, esophagitis, or esophageal spasm can arise with abdominal symptoms. Mesenteric ischemia (“abdominal angina”) should be considered, especially in older patients and those with underlying vascular disease or atrial fibrillation. Aortic dissection, other intra-abdominal processes such as the biliary tract and pancreatic disease, and atypical presentation of an acute cardiac syndrome or other intrathoracic process should be considered in the differential diagnosis. Finally, abdominal pain may be the presenting symptom in psychiatric patients with somatoform disorder. These patients have an altered perception of visceral pain and have an increased sensation of pain when the stomach or small intestine is dilated.

Management

The initial treatment of presumptive PUD includes lifestyle changes (cessation of smoking and the use of alcohol and aspirin). Although the initiation of a bland diet with frequent small feedings is frequently recommended, no study has proven its effectiveness, and the only dietary recommendation should be to avoid foods that are known to exacerbate symptoms. Because PUD is a result of either infection with *H. pylori* or NSAID use, initial treatment should be based on the presumed cause. For NSAID-related ulcers, treatment should begin by discontinuing the offending agent and beginning a PPI.

If NSAIDs are not being used by a patient with suggested PUD, it is currently recommended to treat for *H. pylori* infection. Dyspeptic symptoms without proven ulcer may also be an indication for treatment, but that decision may best be left to a gastroenterologist. Antacid therapy may be started with a PPI or H₂-blocker. Nonendoscopic testing for *H. pylori* is available in the form of antibody detection, urea breath test, and fecal antigen tests; however, their role in the evaluation of ED patients is not yet defined.

Some recommended regimens combine antibiotics with acid-suppressing agents for treatment of *H. pylori* infection (Box 87-3).Commercially available combination products may also be prescribed that may assist in compliance (PrevPac, which contains lansoprazole, amoxicillin, and clarithromycin; and Helidac, which contains bismuth subsalicylate, metronidazole, and tetracycline). Most gastroenterologists recommend continued therapy with antisecretory agents following the antibiotic-containing regimens.

H₂-blockers have not been demonstrated to prevent the formation of ulcers when given concurrently with NSAID therapy; PPIs have been demonstrated to be of some benefit and should be used in patients with gastroduodenal ulcers who must continue using NSAIDs.⁵⁷

GASTRIC VOLVULUS

Perspective

Gastric volvulus is a rare cause of severe abdominal pain that occurs when the stomach rotates upon itself more than 180 degrees, creating a closed-loop obstruction. Only 400 cases have been reported in the literature, although its true incidence is unknown because some types of volvulus are intermittent and resolve spontaneously. It most commonly occurs in persons 40 to 50 years of age and is usually associated with the presence of a paraesophageal hernia. Approximately 20% of cases occur in infants younger than 1 year and are due to congenital diaphragmatic defects. If an acute volvulus is not identified and corrected early, it may lead to gastric ischemia, perforation, and death. The mortality rate from acute gastric volvulus is 15 to 20%.

Principles of Disease

The stomach is fixed at only two points: the esophagocardiac junction and the pylorus. The remainder of the organ is relatively distensible and mobile and can occupy various positions within the abdomen. When a person is supine, the stomach lies entirely above the umbilicus, whereas it descends below the umbilicus in the erect position. Regardless of its position, the stomach maintains its familiar morphology because of ligamentous attachments to the surrounding organs. A primary (or subdiaphragmatic) volvulus occurs when the stabilizing ligaments are too lax or are congenitally abnormal in such a way that the stomach is able to twist upon itself. Approximately one third of cases are of this type.

Secondary (or supradiaphragmatic) volvulus occurs in patients with diaphragmatic defects such as a paraesophageal hiatal hernia, an elevated diaphragm, gastric ulcer or carcinoma, diaphragmatic paralyzis, extrinsic pressure on the stomach from other organs, or abdominal adhesions. The combination of one of these factors and ligamentous laxity makes a volvulus more likely.

Gastric volvulus can be classified on the basis of its axis of rotation. The most common form is organoaxial volvulus, which occurs when the stomach twists on its long axis. Less commonly, the stomach folds on its short axis from the lesser to greater curvature and is classified as a mesenteroaxial volvulus. Approximately one third of cases of gastric volvulus are of this type.

Clinical Features

Presenting Symptoms

The presenting features of a gastric volvulus can vary, depending on the type. Primary volvulus may arise with the sudden onset of severe abdominal pain. The upper abdomen may demonstrate marked distention. Patients with secondary volvulus may experience predominant symptoms in the chest, with pain radiating to the back and shoulders along with accompanying dyspnea. The abdominal examination may be unremarkable. Vomiting is usually present and may be persistent and severe. The combination of severe epigastric pain and distention, vomiting, and inability to pass a nasogastric tube (Borchardt’s triad) should increase the likelihood of a gastric volvulus.

A volvulus may be chronic if the rotation is minimal and there is no vascular compromise. Symptoms usually consist of mild intermittent upper abdominal pain. Early satiety, dyspnea, bloating, eructation, and upper abdominal fullness may be present. It is unknown how often a chronic volvulus can lead to an acute volvulus.

Complications

If not recognized, volvulus can lead to bowel ischemia and necrosis of the stomach. Untreated, this may lead to shock and death. Fortunately, the frequency of gastric infarction is low (reported between 5 and 28% for organoaxial volvulus) because of the redundant blood supply of the stomach. Other complications include ulceration, perforation, hemorrhage, pancreatic necrosis, and omental avulsion.

Diagnostic Strategies

A plain abdominal radiograph often demonstrates a large, gas-filled loop of bowel in the abdomen or chest. A barium swallow may help visualize the abnormality. There are no laboratory findings specific for volvulus, although elevations in amylase and alkaline phosphatase have been reported.

Differential Considerations

The differential diagnosis of gastric volvulus includes any disease that can arise with sudden upper abdominal pain and vomiting. Perforated peptic ulcer, gastric outlet obstruction, biliary tract disease, and acute pancreatitis should be considered. Symptoms of a volvulus may suggest an acute cardiac syndrome.

Management

The goal of treatment of an acute gastric volvulus is reduction. Mortality rates increase with delayed diagnosis because of complications of ischemia. Acutely, one should attempt passage of a nasogastric tube, which may occasionally reduce the volvulus. Although its role is somewhat controversial, patients without signs of gastric infarction may undergo an attempt at endoscopic reduction. Following reduction, recurrence is prevented by surgically repairing any predisposing defects.

DYSPHAGIA

Perspective

Precise motor control of the act of swallowing is necessary to ensure that food is successfully transferred from the mouth through the esophagus into the stomach. This includes the muscles of the oropharynx, the upper esophageal sphincter (UES), the body of the esophagus, and the LES. Failure at any one of these levels results in a motility disorder, the primary symptom of which is dysphagia, which literally means “difficulty swallowing.”

Principles of Disease

Normal Physiology

Swallowing is a complex phenomenon requiring both voluntary and involuntary skeletal muscle activity. Control of swallowing is coordinated by the swallowing center in the medulla. Afferent sensory input involves the trigeminal, glossopharyngeal, vagus, and spinal accessory cranial nerves; efferent motor activity travels through the trigeminal, facial, glossopharyngeal, vagus, and hypoglossal cranial nerves. The act of swallowing begins a process of both simultaneous and sequential activity in all three esophageal zones. A rapidly progressive pharyngeal
contraction transfers the food bolus through a relaxed UES into the esophagus, where a moving ringlike contraction begins in the upper esophagus and propagates distally, making the transition from striated to smooth muscle, culminating with the propulsion of the bolus through a relaxed LES. Three mechanisms have been described that regulate the peristaltic wave, ensuring a smooth transition from the striated muscle in the upper esophagus to the smooth muscle of the middle and lower esophagus and coordination of UES and LES activity. These mechanisms are sequential firing of vagal afferents that begin in the brainstem, an intramural neural mechanism that responds to local stimuli, and myogenic propagation of the contraction through the myocytes themselves.60

Physiologically, swallowing can be divided into oral, pharyngeal, and esophageal phases. The oral phase involves preparation of the food bolus by mastication and lubrication. The tongue then propels the bolus into the pharynx by progressive anteroposterior contractions. In the pharyngeal phase of swallowing, events are initiated by delivery of the food bolus to the oropharynx. Voluntary contraction of the pharyngeal muscles seals the nasopharynx by elevation of the soft palate. The oropharynx is sealed by the upward movement of the tongue against the palate. The larynx and hyoid bone are elevated to seal off the respiratory passage. The cricopharyngeus muscle, or UES, relaxes, and the bolus is swept into the esophagus by sequential peristaltic waves initiated in the upper pharynx. During the esophageal phase, the bolus is propelled toward the stomach by sequential peristaltic waves. Peristalsis can be initiated by swallowing or in response to luminal distension of the gut or changes in the pH or osmotic environment of the mucosa. The lower sphincter normally maintains a degree of tone sufficient to prevent reflux of gastric contents. When the food bolus reaches the lower sphincter, the sphincter relaxes to allow passage of the bolus and then regains its degree of resting tone.

Pathophysiology

Disturbances of the interactions between the components of the upper GI tract lead to a motility disorder. The motor disorders of the body of the esophagus are only now beginning to be understood. The major primary esophageal motility disorders are achalasia, diffuse esophageal spasm, hypertensive esophagus (“nutcracker esophagus”), and nonspecific motor disorder. Of these, the only two that are well defined are achalasia and diffuse esophageal spasm. Controversy exists about whether the other entities are true disease states because symptoms are not always associated with manometric abnormalities and correction of the abnormalities does not always result in symptom improvement. Motor disorders may be the primary cause of other esophageal abnormalities such as GERD or esophageal diverticula.

Clinical Features

Dysphagia at any age is abnormal and requires evaluation. The dysphagia should be classified into one of two types: oropharyngeal dysphagia (also known as transfer dysphagia), related to disease in the pharynx or upper esophagus, or esophageal dysphagia, which is due to disease in the esophageal body or lower esophageal sphincter. Although dysphagia has many causes, a thorough history reveals the diagnosis in most patients (Box 87-4). One should determine where the bolus sticks; the duration of the dysphagia and whether symptoms are intermit-

LES, lower esophageal sphincter.
tient or progressive; whether solids, liquids, or both are involved; whether it is associated with pain; and whether the patient has any previous gastroesophageal history (e.g., esophageal reflux). Any family history of neurologic disease should be obtained.

The examination should include a thorough evaluation of the head and neck and a detailed neurologic examination. The patient should be observed while swallowing. Difficulty in initiating the swallow, misdirection of the bolus with regurgitation or aspiration, and unusual posturing of the patient when swallowing should be noted. Many patients with neuromuscular disorders depend on gravity to swallow, and having the patient swallow in the prone position may be helpful in diagnosis.

Oropharyngeal Dysphagia

Oropharyngeal causes of dysphagia inhibit the initiation of swallowing. Patients complain that “food gets stuck” on swallowing, often pointing to the cervical region when describing their symptoms. Coughing, choking, or drooling may be associated. Neuromuscular diseases cause approximately 80% of oropharyngeal dysphagias, with most remaining causes being localized structural lesions. Most neuromuscular causes of dysphagia result in misdirection of the bolus, sticking, and the need for repeated swallowing attempts. Patients may drool and turn the head and neck to the side to facilitate swallowing.

Delayed aspiration can occur with pharyngeal weakness and or a fixed larynx can result in laryngotracheal aspiration. Inefficient laryngeal elevation from muscular weakness or aspiration, and unusual posturing of the patient when swallowing should be noted. Many patients with neuromuscular disorders depend on gravity to swallow, and having the patient swallow in the prone position may be helpful in diagnosis.

Esophageal Dysphagia

Dysphagia from upper esophageal lesions is usually perceived 2 to 4 seconds after the initiation of swallowing. Dysphagia that the patient localizes to the substernal or retrosternal area may be anatomically accurate, but localization to the neck may be referred from anywhere in the esophagus.

Esophageal dysphagia can be caused by mechanical lesions or a motility disorder. Mechanical lesions include strictures, webs, rings, tumors, esophagitis, or postsurgical changes. Pressure from extrinsic lesions such as osteophytes, mediastinal masses, or aortic aneurysms can also cause dysphagia.

Patients with esophageal dysphagia who have no readily identifiable cause may have a motor disorder. The motor disorders include achalasia, diffuse esophageal spasm, nutcracker esophagus, and hypertensive LES. Achalasia is a disorder of unknown cause in which the resting pressure of the LES is markedly increased and peristalsis in the body of the esophagus is absent. Although it can occur at any age, most patients are between 20 and 40 years of age. Dysphagia is the most common presenting symptom and usually begins insidiously with equal frequency for solids and liquids. Patients may report that maneuvers that increase esophageal pressure (raising arms above the head, standing erect with back straight) help pass the food. Odynophagia from esophageal spasm may also be seen early in the course of achalasia. The symptoms are often worse with rapid eating and during periods of stress. The patient may also report chest pain as a symptom. As dilation occurs above the sphincter, retention of undigested food in the esophagus occurs, and the patient may be aware of gurgling while eating. Regurgitation of the undigested material can occur after a meal (prompting consideration of the diagnosis of an eating disorder) or with changes in position or vigorous exercise. The regurgitated food usually has no acid taste, although bacterial contamination may lead to fermentation of the undigested food. Laryngotracheal aspiration may occur, especially at night, and may cause nocturnal coughing. Physical examination is usually unremarkable except for weight loss. Radiographically, a dilated esophagus is seen proximal to a narrowed gastroesophageal junction that has a beaklike appearance.

The second type of intrinsic motor disorder of the esophagus is diffuse esophageal spasm. Manometrically, simultaneous prolonged strong esophageal contractions are noted to be interspersed over normal peristaltic waves. If a barium swallow is obtained during a spasm, findings such as a “coarse screwing,” or curling, of the esophagus may be noted. Diffuse spasm may be precipitated by swallowing very hot or cold liquids. Symptoms include chest pain, dysphagia, or both.

Nutcracker esophagus is the term used to describe prolonged, high-intensity peristaltic waves. Many experts feel that this represents a variant of diffuse esophageal spasm. Nonspecific motor disorder includes repetitive esophageal contractions, nontransmitted esophageal contractions, or low-amplitude esophageal contractions.

Diagnostic Strategies

Given the myriad causes of dysphagia, a careful history and physical examination are essential. Patients with oropharyngeal dysphagia should have laboratory studies and central nervous system imaging as indicated. Nasopharyngoscopy may also be performed to rule out obvious structural abnormalities. If these are nondiagnostic, patients may be referred for a swallowing study (videoesophagram). Patients with esophageal dysphagia in whom carcinoma, radiation or caustic injury, or achalasia is suggested should undergo a barium swallow. If a
motor disorder is suggested, a swallowing study may prove helpful as well, but this may not detect intermittent dysfunction. In such cases, referral to a gastroenterologist for manometric examination may be required. At that time, additional provocative studies can be performed.

### Differential Considerations

The differential diagnosis of lower esophageal dysphagia includes acute coronary syndromes. Substernal chest pain is the main symptom in 80 to 90% of patients with esophageal motility disorders. The chest pain can be similar to angina, described as crushing or squeezing with patterns of radiation similar to those of cardiac chest pain. Nitroglycerin may relieve the pain of spasm as well, further confusing the picture.

Symptoms that suggest an esophageal etiology of chest pain are pain that is prolonged and nonexertional, pain that interrupts sleep, pain related to meals, relief with antacids, and presence of other symptoms of esophageal disease such as heartburn, dysphagia, or regurgitation. Because of considerable overlap in symptoms, the emergency physician must exclude a cardiac diagnosis before attributing chest pain to an esophageal cause.

### Management

Appropriate management of dysphagia is based on the identified or suggested cause. Most patients with no readily identifiable cause can be evaluated as outpatients; however, it is prudent to admit patients who are at high risk for aspiration. Patients in whom an esophageal motility disorder is suggested should be referred to a gastroenterologist because the diagnosis is usually made manometrically. Achalasia is the only motility disorder for which reasonably good studies support specific treatment. Pharmacologic therapy is directed at decreasing the tone of the LES. Nitrates and calcium channel blockers have been used with some success; however, reflux symptoms may be exacerbated. Other therapies used with some degree of success have included botulinum toxin injection, pneumatic dilation, and surgical intervention.

Medical therapy of esophageal motility disorders is rather limited, and clinical results are usually minimal. Anticholinergic drugs such as hyoscyamine sulfate (Levsin) or dicyclomine (Bentyl) have been used because they decrease the amplitude of esophageal peristalsis and LES pressure. These drugs may also exacerbate reflux symptoms because they cause delayed gastric emptying and decreased esophageal peristalsis.

Calcium channel blockers decrease both LES pressure and the amplitude of esophageal contractions. Nifedipine has been used successfully in some patients. Diltiazem has been shown to be effective in treating nutcracker esophagus. Verapamil has been shown to decrease LES pressure when administered IV to healthy volunteers, but no effects have been noted with an oral dose. Psychotropic medications such as alprazolam and trazodone have been used to treat some esophageal motility disorders. Although no study has demonstrated specific beneficial manometric effects, it is believed that the improvement may be secondary to treatment of an underlying functional disorder such as panic attacks or depression.

#### PHARMACOLOGIC AGENTS FOR UPPER GASTROINTESTINAL DISORDERS

**Antacids**

By the time most patients present with upper GI complaints, most have already tried some form of antacid therapy because these agents are readily available as over-the-counter preparations. Antacids afford pain relief in most patients with PUD. Doses with low neutralizing capacity (as low as 30 mEq) promote ulcer healing. Antacids may also work by binding bile acids or inhibiting pepsin.

The choice of antacid should be individualized. The magnesium-containing antacids can produce diarrhea in up to 25% of patients. Magnesium-containing antacids can also lead to an increase in serum magnesium levels and should be avoided or used with caution in patients with impaired renal function. Aluminum-containing antacids may lead to constipation, and prolonged use may lead to phosphate depletion. Calcium-containing antacids have been marketed both as neutralizing acid and as a means of calcium supplementation, especially for postmenopausal women. Calcium-containing antacids have been traditionally believed to cause the most acid rebound, a paradoxical increase in gastric secretion and acid production. Calcium antacids can also lead to constipation, and their excess consumption can lead to hypercalcemia, alkalosis, and renal insufficiency (the milk-alkali syndrome).

Antacids can also decrease the absorption of warfarin, digoxin, some anticonvulsants, and some antibiotics. The recommended dose of antacids in the treatment of PUD is 400 mmol/day divided over four doses, usually delivered 1 and 3 hours after meals and at bedtime. Antacids are the least expensive drugs available to treat PUD, but their use is somewhat limited by side effects and inconvenient dosing schedules.

#### Histamine Blockers

Histamine is the primary stimulus to gastric acid secretion. It binds to the type 2 histamine receptor (H2) located on the basolateral portion of the parietal cell to stimulate the release of hydrochloric acid. The discovery of the ability of H2-blockers to inhibit gastric acid production was a major advance in antulcer therapy because ulcers cannot develop in the absence of acid. These drugs are highly selective competitive inhibitors of histamine for the H2-receptor on parietal cells and reduce both the volume of gastric juice and its hydrogen ion concentration. All of the currently available H2-blockers are rapidly absorbed after an oral dose, reaching peak levels within 1 to 2 hours. All have half-lives of approximately 2 to 3 hours, so the effects last for about 6 hours. Most are now available over the counter in lower dosage strength. H2-blockers are effective in treating duodenal ulcer and, to a lesser extent, gastric ulcer, although they are not as effective as the PPIs. They are widely prescribed for symptoms of dyspepsia and work well in patients with episodic heartburn. All H2-blockers are mainly hepatically and renally metabolized with the exception of nizatidine, which is almost exclusively renally metabolized. Dosages of all these agents should be reduced in patients with renal failure.

H2-blockers are safe and generally well tolerated. Side effects are rare, including central nervous system effects such as somnolence, dizziness, and confusion. Transient increases in liver enzyme levels may be noted. Some patients may exhibit abnormalities in cardiac conduction, as there are H2-receptors in the heart. Cimetidine has been shown to cause gynecomastia. Dosing of the various agents is summarized in Table 87-1.

#### Proton Pump Inhibitors

The H+, K+-ATPase (proton pump) is located on the apical portion of the parietal cell and is responsible for the production of hydrogen ions in gastric acid. PPIs are the most potent
inhibitors of gastric acid secretion. They work by irreversibly binding to stimulated proton pumps to block secretion of hydrogen ions. Although they have no effect on the volume of gastric juice produced, production of acid can be reduced by up to 95%. Both basal and stimulated gastric acid secretions are reduced. The antisecretory effects last up to 72 hours. PPIs should be administered before the first meal of the day, as the number of proton pumps is maximized after a fasting state. At the cellular level, additional proton pumps are continually recruited to produce more acid in response to stimulation; therefore, several doses of a PPI are necessary to achieve maximal antacid effect. The use of these medications on an as-needed basis would not be expected to provide a good clinical response. H₂-blockers are more suitable for this purpose.⁶⁹

PPIs are hepatically metabolized, and dosage should be modified in patients with hepatic failure. Side effects are usually minimal. Although there are questions regarding the safety of long-term acid suppression leading to hypergastrinemia and hypochlorhydria, the 15-year experience with omeprazole has not demonstrated any clinically significant consequences.⁷⁰ PPIs may be used at significantly higher dosages in patients with Zollinger-Ellison syndrome. Dosing of the various agents is summarized in Table 87-2. Lansoprazole, pantoprazole, and esomeprazole are available as IV formulations.

### Prostaglandins

Prostaglandins exert protective effects on the gastric mucosa by inhibiting acid secretion and decreasing the amount of cyclic adenosine monophosphate generated in response to histamine. Inhibition of gastric acid secretion, increased secretion of mucus and bicarbonate, and stimulation of mucosal blood flow have all been demonstrated.⁷¹ Misoprostol (Cytotec) is an analogue of prostaglandin E₁, with a longer duration of action and greater potency than endogenous prostaglandins. It should be used only for prevention of NSAID-induced gastric ulcers in patients at high risk. The dose is 200 µg four times a day with food, but crampy abdominal pain and diarrhea may require the use of a somewhat less effective dose of 100 µg four times a day.⁷² Misoprostol is an abortifacient and therefore is contraindicated in any female patient of childbearing age who is not using contraception.

### Other Agents

Sucralfate (Carafate) binds to epithelial cells and especially to ulcerated surfaces, providing a protective layer that inhibits further acid damage. Its mechanism of action is not completely understood, although it has been shown to enhance epithelial growth, suppress acid secretion, and inhibit growth of *H. pylori*. The usual dose is 1 g four times a day given 30 to 60 minutes before meals.

Bismuth compounds such as bismuth subsalicylate (Pepto-Bismol) decrease pepsin activity, increase mucus secretion, and form a barrier to further acid damage in ulcer craters. They also increase prostaglandin synthesis and retard hydrogen ion diffusion through the mucosal barrier. Bismuth may also help heal ulcers through its bactericidal action on *H. pylori*. Bismuth compounds are not approved for the treatment of peptic ulcers.

### KEY CONCEPTS

- The combined use of glucagon and an effervescent agent can cause rapid relief of acute lower esophageal obstruction in up to 75% of patients. Radiographic contrast studies of patients with suggested perforation of the esophagus or stomach should first be performed with water-soluble agents such as Gastrografin.
- There is a growing role for nonsurgical management of esophageal perforation for selected low-risk patients.
- GERD treatment includes lifestyle modification and therapy with an antisecretory agent, usually a PPI.
- Peptic ulcer disease results primarily from NSAID use or infection with *H. pylori*.
- Proton pump inhibitors are the most effective means of suppressing gastric acid secretion.

HEPATIC DISORDERS

■ GENERAL PERSPECTIVE

The liver is one of the largest organs in the body, serving a multitude of critical functions. The average weight of the normal adult liver is 1500 g. It receives approximately 30% of the resting cardiac output by way of the portal vein and the hepatic artery.

The liver can be affected by a variety of disorders, and because of its varied synthetic and metabolic functions, liver disease may manifest with a broad range of clinical signs and symptoms. Acute and chronic diseases of the liver are common in the general population and represent a common cause for presentation to the emergency department (ED).

■ HEPATITIS

Perspective

Hepatitis is a generic term referring to inflammation of the liver. Hepatitis most commonly is a consequence of viral infection but can be secondary to bacterial, fungal, or parasitic infection; a result of toxic exposure; a side effect of prescribed medication; or a consequence of an immunologic disorder. Hepatitis in its generic context represents the most common variety of liver disease encountered by the emergency physician.

Viral Hepatitis

Although many viruses are associated with some degree of measurable liver inflammation, the most significant and potentially severe cases of viral hepatitis are caused by type A (infectious), type B (serum), type C (post-transfusion), and delta viruses. Although the Epstein-Barr virus, the causative agent of mononucleosis, is a common cause of hepatitis, it is more important clinically for its nonhepatic effects.

Epidemiology. The number of cases of hepatitis A has declined steadily, from a rate of 11.7 cases per 100,000 in 1997 to 1.5 per 100,000 population in 2005.1,2 Western states had historically shown a higher incidence of hepatitis A, which in 1999 led to routine vaccinations of children from these areas. The greater decline in incidence of hepatitis A among children has resulted in an relative increase in the proportion of cases among adults.3 The number of reported cases of hepatitis B declined by more than 80% in the interval between 1990 and 2005, again with the greatest decline occurring among children younger than 15 years of age.3 The number of new cases of hepatitis C declined by approximately 80% during this period.2 The reduced rates of hepatitis A and B are most likely to reflect today’s broad use of effective vaccines.3,5 Since the late 1980s, the incidence of acute hepatitis C has declined, as a consequence of improved blood product screening. A majority of cases occur among adults, with injection drug use recognized as the most common risk factor.3

Hepatitis A virus (HAV), the causative agent of hepatitis A, is an RNA enteroviral picornavirus. It is spread by the fecal-oral route either directly or through contaminated water or foodstuffs. Transmission by blood is a theoretical possibility but is exceedingly rare. HAV can occur sporadically but is notorious for its association with epidemics generally linked to common source outbreaks. HAV infection is common worldwide; serologic evidence of previous infection exists in nearly 100% of the adult population in some regions. In the United States, close to one half of all urban-dwelling adults are seropositive for antibody for HAV.2 High rates of seropositivity in association with the relatively small number of reported episodes support the notion that many cases may be asymptomatic. Occult disease appears to be more common in children, and 70% may be asymptomatic.5 The incidence of hepatitis A infection varies among ethnic groups. In the United States, the incidence among different geographic areas and ethnic groups has changed notably since targeting of endemic areas with routine vaccination of children. In 2005, recommendations on immunization expanded to include routine vaccination of children in all 50 states.6 These declines have shifted the pattern of reported risk factors, showing an increasing proportion of cases among adults—specifically, men who have sex with men (MSM), illicit intravenous drug users, and non–injection drug users. The most common risk factor for persons older than 15 years of age is travel.5,6

The typical incubation period for hepatitis A is 30 days, with a range of 15 to 45 days. Viremia is of relatively short duration and is most prominent before the onset of symptoms. Fecal shedding and maximum infectivity occur before the onset of symptomatic disease and generally have waned by the time jaundice appears (Fig. 88-1). HAV is not associated with a chronic carrier state.

Hepatitis B virus (HBV) is contained in a 42-nm structure called the Dane particle. Within this enveloped virion is the viral DNA, DNA polymerase, hepatitis B surface antigen
(HBsAg), and hepatitis B core antigen (HBcAg). Hepatitis B e antigen (HBeAg), detectable in the serum of infected patients, is thought to be a degradation product of HBcAg. In contrast with HAV, for which there is only a single antigenic variety, several genotypes of HBV, as defined by surface antigen, are recognized. HBV is transmitted principally by parenteral exposure but also can be transmitted through intimate contact. The highest rates of infection are among illicit intravenous drug users and homosexual men. Transmission by blood transfusion, previously a common source of infection, has been eliminated because of modern blood bank screening techniques.

HBsAg has been detected in a variety of bodily secretions, including saliva, semen, stool, tears, urine, and vaginal secretions. Although the presence of HBsAg is not synonymous with infectivity, HBV DNA has been identified in several of these fluids and is likely to be infectious. The typical interval between exposure and onset of clinical illness is between 60 and 90 days; however, serologic markers of infection generally appear within 1 to 3 weeks (Fig. 88-2). Approximately 10% of adults and 95% of infected neonates with immature immune systems will become asymptomatic chronic carriers of HBsAg. Health care workers who routinely come in contact with blood have a prevalence of HBsAg of 1 to 2%, and 15 to 30% show serologic evidence of previous infection. Among emergency physicians, seropositivity rates of 12% and 15% have been reported. The likelihood of becoming chronically infected with HBV varies inversely with the age at which infection occurs. HBV transmitted from HBsAg-positive mothers to their newborns results in HBV carriage in up to 90% of infants, whereas only 6 to 10% of acutely infected adults become carriers. Approximately 3 to 5% of the cases of hepatitis B will progress to chronic hepatitis.

What was historically referred to as non-A, non-B hepatitis is caused by at least two distinct RNA viruses, hepatitis C virus and hepatitis E virus. Hepatitis C, linked to transfusions, is common in the United States. Hepatitis E, which is associated with fecal-oral transmission, is encountered most often in Asia, Africa, and Russia. The historical risk of hepatitis in patients receiving blood transfusions was approximately 0.45% per unit transfused. The screening of donor blood for surrogate markers (aminotransferases) and antibody to hepatitis C has decreased this risk to less than 1 per 1 million transfused units. The estimated risk of transfusion-transmitted HCV is now 1 per 103,000 transfusions. Although hepatitis C is most often associated with transfusions, only 10% of patients with this disease report a previous history of having received blood or blood products. Approximately 4 to 8% of cases are linked to occupational exposure in health care workers, and 25 to 42% are associated with intravenous drug use. Among patients infected with HIV, the incidence of co-infection with hepatitis C is 15 to 30%. This rate approaches 50 to 90% in those who acquired HIV through intravenous drug use (IVDU). Patients co-infected with HIV and HCV generally will have a more aggressive course of both their HIV and HCV infections. In 40 to 57% of cases of hepatitis C, no source of infection is identified. The incubation period for hepatitis C is 30 to 90 days, with a mean of 50 days. Hepatitis E has an incubation period of 15 to 60 days. Approximately 90% of HCV infections go on to become chronic hepatitis. Long-term follow-up studies indicate that clinical liver disease develops in only 10 to 20% of those infected during a period of approximately 20 years after transfusion. In the United States, it is estimated that 2.7 million people are chronically infected with HCV.

Hepatitis delta virus (HDV) was discovered in 1977 in liver specimens from patients with chronic HBV infection. It is a defective RNA virus that can infect only patients who are actively producing HBsAg, which is required for its viral coating. In the United States, the incidence of HDV antibody is between 4% and 30% of patients with chronic HBV infec-
The clinical presentation of viral hepatitis is critically important in diagnosing and determining the specific cause. The most useful tests are measurements of the hepatic aminotransferases and bilirubin. Typically, hepatitis is associated with elevations (10- to 100-fold) of serum aspartate aminotransferase (AST) and alanine aminotransferase (ALT), with ALT generally elevated in excess of AST. Bilirubin may be moderately increased (5 to 10 mg/dL) and occasionally is markedly elevated (15 to 25 mg/dL). Hyperbilirubinemia typically emerges several days to a week or more after the onset of clinical symptoms. Both direct and indirect bilirubin levels are elevated in close to equal proportions. Alkaline phosphatase and lactate dehydrogenase may be elevated but rarely are more than two to three times normal. Prothrombin time (PT) or international normalized ratio (INR) is useful in assessing the degree of hepatic synthetic dysfunction. Elevation of the PT or INR may be the first clue to a complicated course. The white blood cell count (WBC) generally is not useful in the diagnosis because values range from low overall counts with a lymphocytic predominance to marked polymorphonuclear leukocytosis.

Although determination of the precise cause of hepatitis can rarely be achieved in the ED, this evaluation should be initiated as soon as possible. Identification of the causative agent has significant impact on prognosis and public health issues. In this regard, it is important to be able to interpret the significance of certain serologic tests (Table 88-1).

Acute hepatitis A is diagnosed by the presence of immunoglobulin M (IgM) HAV antibody, whereas previous infection is determined by detection of an immunoglobulin G (IgG) antibody. Acute hepatitis B is characterized by the presence of HBsAg and IgM antibody to HBcAg. HBsAg alone does not establish the diagnosis of acute hepatitis B because it can be either absent late in the course of acute disease or present chronically unrelated to the cause of the current episode. Anti-HBcAg antibody generally is the best indicator of previous HBV infection, whereas anti-HBsAg antibody is the best marker for immunity to HBV.

Currently, the diagnosis of hepatitis C is based on the exposure history and the elimination of other causes. The serologic assay for an antibody to this virus facilitates a definitive diagnosis, but there can be a delay between the onset of symptoms and the development of assayable antibody. Furthermore, the HCV test does not distinguish acute from chronic infection.

Diagnosing HDV infection requires an aggressive search because the disease can easily be mistaken for acute or chronic HBV infection. A serologic test for the antibody to HDV (anti-HDV) is available. The presence of this antibody in conjunction with IgM antibody to HBcAg suggests co-infection with HDV and HBV. Anti-HDV in association with IgG antibody to HBcAg supports the diagnosis of superinfection.

The temporal relationships among infection, clinical symptoms, and serologic responses for the two most common causes of viral hepatitis, HAV and HBV, are delineated in Figures 88-1 and 88-2.

**Differential Considerations.** The protean nature of the symptoms and signs associated with viral hepatitis makes the differential diagnosis of this disorder quite broad in scope. Beyond a variety of nonhepatic viral illnesses, all of the infectious, chemical, and immunologic causes of hepatic inflammation in addition to biliary tract disease must be considered. A viral cause often is suggested by the exposure and medical history but requires serologic tests for confirmation. Alcoholic hepatitis...
usually is associated with a history of chronic or excessive alcohol consumption, less marked elevation of hepatic transaminases, and AST levels elevated above those of ALT. Extrahepatic obstruction, cholecystitis, and cholelithiasis are excluded by their lack of association with significant elevation of aminotransferases; however, abdominal ultrasound studies may be required to eliminate these other causes. 

Management. Treatment of viral hepatitis is primarily symptomatic. It often is necessary to correct fluid and electrolyte imbalances secondary to poor oral intake or excessive diarrhea or vomiting. Antiemetics may allow resumption of adequate oral intake, thereby avoiding the need for hospital admission. In the anorectic or nauseous patient, fluid intake should be encouraged, with avoidance of solids until they are palatable. Medications requiring primarily hepatic metabolism generally do not need to be discontinued nor the dosage modified unless there is significant hepatic dysfunction. Nonessential drugs with hepatotoxic potential should be avoided. Alcohol consumption should be completely discontinued until signs of liver injury have disappeared. Although a variety of active interventions (e.g., corticosteroid administration) have been suggested, no reliable data suggest that such therapies offer clear benefit; they may even be harmful.

Complications of acute hepatitis are most commonly related to fluid or electrolyte imbalance as a result of inadequate oral intake or refractory emesis. Severe vomiting can result in upper gastrointestinal (GI) bleeding from an esophageal tear. The most severe complication of acute disease is the development of liver failure heralded by the emergence of hepatic encephalopathy. Most patients with viral hepatitis have self-limited disease, with symptomatic and histologic resolution in 2 to 4 weeks. Chronic disease will develop in approximately 10% of patients with hepatitis B and in as many as 50% of those with hepatitis C.19 Clinical liver disease develops in only 10 to 20% of chronically infected patients approximately 20 years after becoming infected. Many of these patients will eventually die of cirrhosis secondary to their disease.19

Disposition. Hospital admission is rarely required for management of viral hepatitis and generally is reserved for the patient with significant fluid and electrolyte imbalance or refractory vomiting. Patients with less severe illness may require hospitalization for concomitant medical problems or if suitable living arrangements are not available. Altered sensorium, prolongation of the PT beyond 5 seconds or increase in the INR above 1.5 may suggest fulminant disease or an increased likelihood of a complicated course, necessitating hospitalization for observation. The emergence of fulminant disease should lead to consideration of transfer to a facility that can offer liver transplantation.

Treatment with interferon alfa-2b has resulted in a 35 to 45% remission rate after a 4-month course of treatment in selected patients with active immune responses in the symptomatic stage 2 period of hepatitis B infection.10,30,31 Hepatitis C treatment recommendations suggest that duration of treatment with interferon and ribavirin should be based on the HCV genotype and pretreatment viral load. Polyethylene glycol added to interferon alfa (peginterferon alfa) extends the half-life and duration of the therapeutic activity of the interferon. Corresponding clinical benefits include both a higher rate of response than with conventional daily interferon monotherapy and feasibility of once-weekly administration.32 Referral to a hepatic disease specialist is recommended.

Anxiety about disease communicability may affect the ease of disposition. Patients with possible HAV infection should be advised to practice meticulous personal hygiene, not to share toiletries, and to ensure cleaning of utensils and kitchenware between uses. In those patients with suspected HBV or HDV infection, the relatively low risk of transmission in lieu of intimate personal contact or parenteral exposure should be emphasized.

Viral hepatitis is a reportable disease requiring notification of the local health department. Immunoprophylaxis should be provided to the patient’s family members and close personal contacts. Although the nature of prophylaxis depends on the specific viral cause, it is wise to offer gamma globulin to household contacts immediately unless they are known to have been previously immunized, pending serologic determination. Table 88-2 outlines the guidelines for immunoprophylaxis. Patients with HAV infection who process or handle food must not return to work while potentially infectious. Although infectivity is greatly diminished by the time jaundice emerges, it is best to delay return to work until after jaundice has cleared.

Special Considerations

Effective pre-exposure and post-exposure prophylaxis for HBV has been available for over 2 decades. The rates of sero-positivity for HBV infection among health care workers have historically been high compared with those in the general population.
population. Health care workers in an ED are at increased risk because of frequent contact with blood and interaction with high-risk patients. Historically, the seropositivity rate among ED nurses is 30% and among ED physicians is between 12% and 15%. The 1-year risk of infection among nonimmunized emergency physicians is approximately 0.25%, with a 30-year risk approaching 7.5%. During a 30-year career, the risk of death from hepatitis B is estimated at 1/540. Markers for hepatitis C were identified in 18% of patients in an inner-city ED; the potential associated health risk to staff is unknown.

All ED personnel involved in patient care or custodial work should be vaccinated for HBV before or soon after employment. The vaccine is highly effective and associated with minimal acute or delayed toxicity. A complete three-injection series of vaccine produces protective antibody in approximately 95% of persons. Optimal immunologic response is obtained with deltoid injection. HBIG dose: 0.06 mL/kg IM. HB, hepatitis B; HBIG, hepatitis B immune globulin; HBsAg, hepatitis B surface antigen; ISG, immune serum globulin.

No treatment

Administer HBIG² HB vaccine³

¹High risk defined as exposure to patient in one of the following groups: homosexual men, intravenous drug users, recent emigrés from endemic region.

²HBIG – 0.06 mL/kg IM, as soon after exposure as possible, no later than 7 days past exposure.

³HB vaccine – 1 mL IM deltoid, refer for completion of series to include three injections total, test for response within 60 days of last vaccination.

Figure 88-3. Management of health care workers exposed to blood or other infectious secretions. Ab, antibody; Ag, antigen; HB, hepatitis B; HBC, HB core; HBIG, HB immune globulin; HBs, HB surface.
The risk of seroconversion after percutaneous exposure from an HCV-positive source is approximately 1.8%.\textsuperscript{17} Despite the theoretical risk of blood-borne HCV exposure among health care workers, the prevalence of HCV infection in this group is approximately 1 to 2%, the same as in the general population.\textsuperscript{17} No effective vaccine for HCV is available, and despite evidence to suggest effectiveness of interferon in acute hepatitis C, there is no accepted pre- or post-exposure prophylaxis regimen.\textsuperscript{48}

Universal precautions—the use of gloves, masks, protective eye wear and gowns—constitute the first and best means of defense for persons who work in proximity to potentially infective bodily fluids.

### Key Concepts

- Viral hepatitis is a common disorder that can be caused by several agents.
- Clinical presentation is highly variable, and many cases, particularly in children, are asymptomatic.
- The process of identifying the etiologic agent should be initiated in the ED because it affects both prognosis and public health interventions.
- Many of the etiologic agents of viral hepatitis represent a potential threat to health care workers, necessitating proper precautions in handling potentially infectious body fluids and pre- and post-exposure prophylaxis.

### Alcohol-Related Liver Disease

**Perspective.** In the United States, an estimated 15 million to 20 million people are chronic alcoholics.\textsuperscript{39} Alcohol and its metabolites are toxic to most organ systems and contribute to disease or death from many different causes. The liver is the most common site of injury from chronic ethanol ingestion. Alcoholic liver disease is ranked as the fourth leading cause of death among men aged 25 to 64 years living in urban areas. Cirrhosis, most commonly linked to chronic alcohol consumption, is a common cause of death and years of productive life lost.\textsuperscript{40}

**Principles of Disease.** Alcohol is largely eliminated by metabolic degradation in the liver. Approximately 2 to 15% of alcohol is excreted unchanged in the urine or expired air.\textsuperscript{34} The precise pathogenesis of alcoholic liver disease is unknown and probably is multifactorial. Coexistent malnutrition, accumulation of toxic metabolites (e.g., acetaldehyde), excessive production of nicotinamide adenine dinucleotide (NADH) and induction of microsomal enzymes due to the metabolism of alcohol, and alteration of immune function all may play a role.\textsuperscript{41}

Regardless of the precise mechanism of injury, genetic heterogeneity in susceptibility to liver damage is likely. Women and possibly Native Americans appear to have an increased propensity for injury relative to white men.\textsuperscript{42,43} A study of Portuguese adults identified certain histocompatibility antigens with increased risk of ethanol-related hepatic injury.\textsuperscript{44} Although susceptibility to alcohol varies, a rough correlation is recognized between the amount of ethanol ingested and the risk of developing liver disease. The risk of liver injury increases as daily consumption exceeds 80 g of ethanol daily in men and 20 g in women. For men, this is equivalent to a six-pack of beer, four to six glasses of wine, or three to four mixed drinks daily.\textsuperscript{39}

The most common variety of alcohol-induced liver disease is steatosis. Fatty infiltration of the liver is most likely a consequence of altered fatty acid metabolism resulting from a diminished NAD\textsuperscript{+}/NADH ratio, which favors triglyceride production. Fatty infiltration appears to depend on the duration and amount of alcohol consumed and, in general, is reversible when the patient stops drinking. Beyond enlargement of the liver, which usually is painless, this tends to be a benign process.

**Clinical Features.** Alcoholic hepatitis is a potentially severe form of alcohol-induced liver disease. Most cases probably are subclinical, but the spectrum of presentation can range from nausea, vomiting, and abdominal pain to acute liver failure.

Physical findings include tachycardia, fever, and supine or orthostatic hypotension. Abdominal tenderness usually can be elicited, especially in the right upper quadrant. Coexistent fatty infiltration may produce palpable hepatomegaly; cirrhosis from chronic disease may result in a small, nonpalpable liver.

The characteristic physical signs of cirrhosis (gynecomastia, spider angiomata, muscle wasting, ascites, and palmar erythema) may be present. Jaundice can be noted in patients with a bilirubin level of at least 2.5 mg/dL.

**Diagnostic Strategies.** Laboratory tests reveal moderate elevations of AST and ALT. Values in excess of 10 times normal are unusual, even in severe cases associated with eventual liver failure. Compared with viral hepatitis, a relative predominance of AST to ALT is expected. Bilirubin is commonly elevated. The WBC count often is high, with a polymorphonuclear leukocytosis in the range of 10,000 to 20,000/mm\textsuperscript{3}. The PT and the INR provide a rough assessment of hepatic dysfunction. An acutely prolonged PT or elevated INR in a patient not suspected to have chronic cirrhotic disease suggests a complicated course. Electrolyte or acid-base disturbances may develop as a consequence of excessive vomiting or alcoholic ketoacidosis.

**Differential Considerations.** The differential diagnosis of alcoholic hepatitis is quite broad in scope and includes a variety of other alcohol-related GI maladies (e.g., gastritis, pancreatitis). Patients often have several ethanol-induced diseases simultaneously. Initially, all of the potential etiologic disorders must be considered; however, the clinical history and amino-transferase profile should facilitate accurate diagnosis. Mild aminotransferase elevation and marked bilirubin elevation is consistent with alcoholic hepatitis; ultrasonography will help differentiate this from common duct obstruction. Serum should be sent for testing for anti-HAV IgM and HBcAb IgM, but results usually are not available to establish these diagnoses in the ED.

**Management.** Management of alcoholic hepatitis is principally supportive. Fluid and electrolyte imbalance must be corrected, usually requiring parenteral fluid replacement; antiemetics may mitigate the need for intravenous treatment. Alcohol may suppress gluconeogenesis, thereby causing hypoglycemia. Blood glucose should be measured and supplemented as indicated. Many alcohols are malnourished, and if thiamine deficiency is suspected, it should be given in a dose of 50 to 100 mg IM or IV before glucose administration to avoid inducing acute Wernicke’s encephalopathy. Ethanol-induced magnesium wasting may not be apparent on serum magnesium measurement, and replacement should be given empirically unless the patient has a contraindication such as renal failure or known hypermagnesemia. Magnesium can be given as the sulfate salt in a dose of 1 g IV or IM or as an oxide, chloride salt, or amino acid conjugate for oral replacement therapy in a daily dose of 200 to 1000 mg.

The overall nutritional status of the patient should be addressed with the administration of a high-calorie, vitamin-supplemented diet. Protein content may require restriction if evidence of cirrhosis and incipient encephalopathy exists.
Laboratory tests are not specific. Amino-

The clinical manifestations of cirrhosis are

Clinical

The liver is one of the most common targets of alcohol
toxicity.

Alcoholic hepatitis, although generally a mild disease
with minor clinical manifestations, can be a cause of fulminant hepatitis.

Management of patients with alcoholic hepatitis
should include referral for alcohol dependence treatment.

Cirrhosis

Principles of Disease. Cirrhosis is a generic term for an end stage of chronic liver disease characterized by destruction of hepatocytes and replacement of normal hepatic architecture with fibrotic tissue and regenerative nodules. Laennec’s cirrhosis is a diffuse process that involves the entire lobule and most often is related to chronic alcohol ingestion. From 10 to 20% of chronic alcoholics develop this type of cirrhosis. Amount and duration of alcohol ingestion, heredity, and underlying nutritional status all seem to play some role in the development of this disorder. Postnecrotic cirrhosis usually is nonhomogeneous, characterized by regions of fibrosis and hepatocyte loss alternating with normal areas. It most often is a consequence of chronic hepatitis of various causes: infectious (viral, bacterial, fungal), drug-induced, or metabolic. Biliary cirrhosis is much less common and is a consequence of chronic extrahepatic biliary obstruction or a primary disorder of autoimmune mediated intrahepatic duct inflammation and scarring. Nonalcoholic fatty liver disease has become an increasingly recognized cause of cryptogenic cirrhosis. This still poorly understood disease, with features similar to those of Laennec’s cirrhosis, is more common in obese patients and those with type 2 diabetes mellitus.48

Clinical Features. The clinical manifestations of cirrhosis are related to loss of hepatocytes, leading to metabolic and synthetic dysfunction, or to fibrosis and altered hepatic architecture, resulting in impaired portal vein blood flow and portal hypertension. Typically, the patient with cirrhosis complains of chronic fatigue and poor appetite. With the exception of those with biliary cirrhosis, many patients with cirrhosis can be asymptomatic until some dramatic complication develops, such as GI bleeding, ascites, or hepatic encephalopathy. Patients with biliary cirrhosis generally complain of pruritus or exhibit obvious jaundice before end-stage cirrhosis or complications develop. Primary biliary cirrhosis may be associated with other immune-mediated disorders; these patients may have signs and symptoms characteristic of scleroderma or the CREST syndrome (i.e., calcinosis cutis, Raynaud phenomenon, esophageal motility disorder, sclerodactyly, and telangiectasia).49

Physical examination may reveal muscle wasting, thinning of the skin with patchy ecchymosis, spider angioma, palmar erythema, Dupuytren’s contracture, and in men, gynecomastia or testicular atrophy. Jaundice generally is absent in mild cases or in early disease. The liver may not be palpable if it is extensively scarred, but a large regenerative nodule, tumor, or fatty infiltration can result in hepatomegaly. Ascites is common, particularly in advanced disease, and may be present in association with a characteristic pattern of abdominal wall vein distention known as caput medusae.

Diagnostic Strategies. Laboratory tests are not specific. Aminotransferase levels are rarely more than minimally elevated. Bilirubin may be increased but usually not until cirrhosis is far advanced. Elevation of alkaline phosphatase out of proportion to other liver enzymes is suggestive of biliary cirrhosis. Coagulation studies commonly show abnormalities, and the serum albumin level is low as a result of impaired hepatic synthetic function. Mild to moderate anemia and thrombocytopenia often are present in Laennec’s cirrhosis. Elevated blood urea nitrogen (BUN) or creatinine suggests dehydration or hepatorenal syndrome. Ancillary tests are rarely of use in the ED setting. Ultrasoundography is highly sensitive for the detection of ascites, but a carefully performed physical examination generally can yield equivalent results. Patients with ascites and fever or abdomi-
nal pain should have paracentesis performed to rule out spontaneous bacterial peritonitis (SBP, see later section). Nuclear scintigraphy or computed tomography (CT) imaging may reveal a hepatic or splenic appearance characteristic of cirrhosis and portal hypertension, but in general, these tests should be deferred to an elective setting.

Management. Treatment of cirrhosis in the ED is limited. Fluid and electrolyte imbalances should be corrected, and vitamin and nutritional supplements should be provided. Most patients can be discharged with referral to a general internist for further evaluation and treatment. Ascites associated with respiratory compromise or significant discomfort can be treated with paracentesis and removal of 2 L of fluid or more. Removal of very large quantities of ascitic fluid can result in body fluid and electrolyte abnormalities and hemodynamic instability. If SBP is a consideration, diagnostic paracentesis should be done.

A low-sodium diet, in conjunction with an aldosterone antagonist, may be of use in the chronic management of ascites. A low-dose regimen of a thiazide or loop diuretic may accelerate resolution of ascites and probably is safe if the patient has coexistent peripheral edema and normal renal function. Coagulopathy noted before a planned invasive procedure or in con-
junction with active bleeding should be corrected with fresh frozen plasma. With uncomplicated prolongation of PT or INR, treatment with vitamin K supplementation can be given but often is ineffective. GI bleeding should be treated aggressively. Early consultation with a gastroenterologist for endoscopy often will permit identification of a bleeding site and initiation of appropriate adjunctive treatment. An elevated creatinine level may herald the onset of hepatorenal syndrome and necessitates hospitalization of the patient for optimal fluid and electrolyte management.

Complications of cirrhosis include GI bleeding, ascites with or without infection, encephalopathy, and hepatorenal syndrome. Although GI bleeding often is related to esophageal or gastric varices, more than one half of the cases result from some other source (e.g., gastritis or a duodenal ulcer). Ascites
Hepatic Encephalopathy

Principles of Disease. *Hepatic encephalopathy* is a clinical state of disordered cerebral function that may develop as a consequence of acute or chronic liver disease. The pathophysiology of hepatic coma is complex and related to the diseased liver’s failure to adequately perform its normal metabolic functions. Ammonia, formed primarily in the GI tract by the action of bacteria on proteinaceous compounds, is a common marker of this process. Normally, absorbed ammonia is converted to urea in the liver. In severe hepatic disease, ammonia accumulates, crosses the blood-brain barrier, and combines sequentially with α-ketoglutarate and glutamate to form glutamine. Serum ammonia levels correlate inconsistently with the severity of encephalopathy, but a close association with cerebrospinal fluid (CSF) glutamine levels has been recognized. Whether glutamine is itself toxic or simply represents a marker for disordered central nervous system (CNS) metabolism is unknown. Other agents presumed to play a role in the pathophysiology of this disorder include mercaptans, octopamine, γ-aminobutyric acid, and the aromatic amino acids, particularly tryptophan.

Clinical Features. The clinical manifestations of hepatic encephalopathy vary depending on the severity of the process, ranging from mild cognitive dysfunction, irritability, and confusion to profound coma. Table 88-3 summarizes the four stages of hepatic encephalopathy. Asterixis, a low-amplitude, alternating flexion and extension of the wrist occurring when it is held in extension, is characteristic of mild to moderate degrees of encephalopathy. A similar finding may be elicited in the dorsiflexed foot, or similar head movements may occur with extension of the neck. Feto hepaticus, a musty breath odor presumable from mercaptans, may be detected in severe cases.

Physical examination commonly reveals signs of cirrhosis, including spider angiomata, testicular atrophy, muscle wasting, superficial bruising, gynecomastia, and ascites.

Diagnostic Strategies. Laboratory test results may be normal or indicate fulminate liver failure or chronic cirrhosis. Serum ammonia levels generally are elevated but do not necessarily correlate with the severity of encephalopathy. Results of tests reflective of hepatic synthetic function, serum albumin and PT, generally are abnormal. The electroencephalogram shows abnormalities in most cases, but the pattern of generalization slowing with high-voltage bursts of triphasic or delta waves characteristic of hepatic encephalopathy is not specific for this entity.

Differential Considerations. The differential considerations in patients with suspected hepatic encephalopathy include all causes of altered sensorium. The scope of the differential can be narrowed if the patient’s history includes previous episodes of hepatic encephalopathy or if the patient has severe underlying liver disease and physical signs are supportive. It may be useful to obtain a full electrolyte panel, glucose level, toxicology screen, and, if conditions warrant, a head CT scan and CSF examination to rule out potentially life-threatening conditions.

Management. Aggressive management of the patient with hepatic encephalopathy may reverse the condition. As with any comatose patient, the airway is assessed first, not only to determine the need for respiratory support but also for prevention of aspiration. Affected patients generally are hemodynamically stable but have an increased incidence of GI bleeding. Hypokalemia, alkalosis, and increased ammonia production or absorption, and the cause must be addressed when any of these abnormalities is detected. Relatively mild degrees of hyponatremia, hypoglycemia, azotemia, or dehydration often will have a disproportionate effect on cerebral function and require immediate correction. All CNS-depressant drugs must be discontinued, and care should be taken not to prescribe even mild sedatives.

Lactulose and neomycin are the principal therapeutic agents in the management of this disorder. Lactulose, an osmotic cathartic, is a poorly absorbed sugar metabolized to lactic acid by colonic bacteria. This causes acidification of the fecal stream, resulting in the trapping of ammonia as ammonium in the stool. The usual dosage of lactulose is between 30 and 60 g daily or in a quantity sufficient to result in several loose bowel movements daily. The principal adverse effect is excessive diarrhea, with resultant fluid and electrolyte imbalance. Neomycin is not the usual aminoglycoside. It is believed to act by reducing colonic bacteria responsible for the production of ammonia. Neomycin is administered orally at a dosage of 0.5 g every 4 to 6 hours. Ototoxicity or renal injury may occur in patients with impaired renal function. In obstructed patients, lactulose and neomycin can be administered by nasogastric tube or rectal enema. Long-term management requires diet modification for significant protein restriction.

Alternative therapies, still undergoing clinical evaluation, include the antibiotics metronidazole and rifaximin (to decrease activity of urease-producing bacteria), *Lactobacillus acidophilus* (to increase non–urease-producing bacteria), eradication of *H. pylori* (urease-producing), zinc replacement...
Diagnosis is made by culture of the ascitic fluid. The presence of enteric organisms is diagnostic for SBP. 

**Disposition.** Although most patients with hepatic encephalopathy will require hospitalization, those with grade I or II encephalopathy without complicating factors and a supportive home environment can be managed at home. In addition to a prescription for lactulose, a diet with limited amounts of protein is essential to effective ongoing management.

**Spontaneous Bacterial Peritonitis**

**Perspective.** SBP is an acute bacterial infection of ascitic fluid in patients with liver disease, without an apparent external or intra-abdominal focus of infection. The syndrome is not new, but it was not until the late 1960s and early 1970s that this potentially fatal disorder was commonly recognized. Although the disease occurs most often in patients with cirrhosis due to alcohol, it can occur in any patient with ascites secondary to cirrhosis. 

**Principles of Disease.** The pathophysiology of SBP remains speculative but is most likely to be related to a combination of impaired phagocytic function in the liver and portal systemic hypertension, which can cause bowel mucosal edema and transmural migration of enteric organisms. Additional contributing factors may include impaired activity of opsonins and complement in ascitic fluid. Gram-negative enteric organisms, primarily *Escherichia coli*, are the most frequently identified organism in SBP. 

**Clinical Features.** The clinical presentation can be variable, ranging from the acute onset of severe abdominal pain, fever, chills, and hemodynamic instability to the slow, insidious onset of abdominal discomfort or low-grade fever, or hepatic encephalopathy. Although by definition, ascites must be present for SBP to develop, free peritoneal fluid may not always be clinically apparent. An elevated temperature may not be detected in 20 to 50% of cases. 

On physical examination, palpation may elicit only mild tenderness or may reveal abdominal rigidity and guarding with rebound tenderness. One study identified a positive peritoneal fluid culture rate of 3.5% among patients who were judged to have asymptomatic ascites. This observation underscores the exceptionally broad spectrum of manifestations and often very minimal physical findings with this disorder and the need to consider the diagnosis of SBP in any patient with ascites who presents with abdominal pain or who exhibits unexplained clinical deterioration.

**Diagnostic Strategies.** Diagnosis is made by culture of the ascitic fluid, but treatment decisions should be made in advance of these results. An ascitic fluid granulocyte count greater than 500 cells/mm³ correlates with positive cultures in more than 90% of cases; however, ED treatment for SBP should be initiated if the neutrophil count is greater than 250 cells/mm³. A positive result on urine reagent strip testing for leukocyte esterase has a high degree of correlation with a clinically significant elevation of neutrophil cell count. If ascitic fluid is available for testing, a pH of less than 7.34 or a pH gradient between arterial blood and ascitic fluid of more than 0.10 also is a reliable early indicator of SBP. Other laboratory parameters (e.g., aminotransferase, bilirubin, peripheral blood count) are commonly abnormal, but such findings are nonspecific and more often are a consequence of underlying liver disease than infection. A PT and INR should be measured in advance of paracentesis, and fresh frozen plasma should be administered if significant coagulopathy is identified.

**Differential Considerations.** The differential diagnosis for SBP includes all of those entities that may lead to peritonitis and abdominal pain in patients with or without liver disease. 

**Management.** Treatment of SBP requires intravenous antibiotics. The choice of agents is driven by the anticipated bacteriology of the process. A third-generation cephalosporin such as cefotaxim, which is considered to be the agent of choice, with a documented cure rate of 90%. An alternative is an ampicillin-sulbactam combination. Ampicillin with an aminoglycoside is also effective but is associated with an increased risk of renal toxicity.

**Disposition.** Any patient with ascites is at risk for the development of SBP. This risk is markedly increased in patients with ascitic fluid protein levels less than 1 g/dL. Other important risk factors include serum bilirubin level greater than 3.2 mg/dL, platelet count less than 98,000/mm³, and a previous history of SBP. Antibiotic prophylaxis for high-risk patients can reduce SBP incidence by 60 to 80% and can be cost-effective. The preferred regimen consists of norfloxacin 400 mg daily. The emerging problem of quinolone resistance has prompted investigation of trimethoprim-sulfamethoxazole as an alternative for prevention of SBP. If a high-risk patient with ascites is identified in the ED and contraindications are absent, prophylactic therapy should be initiated. Referral to a primary care physician or gastroenterology specialist is recommended. Patients with diagnosed SBP require hospitalization.

**KEY CONCEPTS**

- SBP should be considered in any patient with ascites presenting with abdominal pain, fever, or unexplained clinical deterioration.
- The diagnosis is dependent on obtaining ascitic fluid for cell count and culture. An ascitic fluid granulocyte count greater than 250 cells/mm³ is an indication for antibiotic treatment. Urine reagent strips that test for leukocyte esterase may provide a convenient means of bedside screening of ascitic fluid for SBP.
- Identification of a high-risk patient with ascites is an indication for initiation of SBP prophylaxis with an orthoquinolone antibiotic.
Drug-Induced Liver Disease

**Perspective.** In addition to alcohol, a variety of other chemical agents can induce injury to the liver. Most of these agents are commonly prescribed medicinals or drugs available over the counter. Although hepatic injury represents a relatively small proportion of all adverse drug reactions, it may account for up to 5% of hospital admissions for jaundice.76 Drug-induced liver disease is one of the most common reasons for market withdrawal of drugs by the U.S. Food and Drug Administration (FDA) and is responsible for approximately 50% of the cases of fulminant liver failure in the United States.77 For reasons not entirely clear, the incidence of liver injury related to drugs appears to increase with patient age. Notable exceptions include valproic acid and aspirin, which more often cause hepatic damage in children.

**Principles of Disease.** The pathogenesis of liver injury from drug exposure is variable. It may occur as a result of a direct cytotoxic effect of the primary agent or, as is more often the case, a major or minor metabolite. Alternatively, toxicity can be related to a hypersensitivity or allergic reaction. Antimetabolites (e.g., azathioprine, comfrey tea) have been associated with hepatic injury caused by veno-occlusive disease; oral contraceptives have been implicated in cases of hepatic vein thrombosis.78,79 Anti-retroviral drug therapy (ARVT) is a common cause of liver toxicity defined by elevations in alanine aminotransferase (ALT) greater than aminotransferase (AST). Increases in ALT or AST of 3.5-fold and 5-fold are considered to represent moderate and severe hepatotoxicity, respectively.80 Mechanisms identified as leading to liver toxicity from ARVT include metabolic host-mediated factors, hypersensitivity, mitochondrial toxicity, and immune reconstitution.80

Not all agents commonly associated with hepatic toxicity will cause injury in all patients. This nonuniformity may be a consequence of variations in metabolic pathways, simultaneous ingestion of other substances that may facilitate toxicity, amount and duration of drug exposure, or patient idiosyncrasy. For example, isoniazid appears to have differential toxicity depending on both the patient’s age and the rate of conversion to a particular toxic metabolite, acetyl hydrazine. Acetaminophen is relatively nontoxic when taken in the usually recommended amounts but universally toxic and potentially fatal when taken in significant excess (see Chapter 146).

In general, drugs that induce liver injury cause hepatocellular necrosis or cholestasis. Although specific agents tend to cause damage characterized by a particular pattern of injury, there is considerable overlap. Cellular necrosis commonly is associated with anesthetic agents (e.g., halothane, the antimicrobials amphotericin and ketoconazole, or the antidyshrhythmic amiodarone). A cholestatic pattern is characteristic of liver injury from chlorpromazine, haloperidol, anabolic or oral contraceptive steroids, or erythromycin estolate.

**Clinical Features.** Many patients with drug-induced liver disease will be asymptomatic, with injury manifested only by moderate elevations of aminotransferase levels. Other patients may experience painless jaundice resulting from agents associated with cholestatic pathology or as a result of acute hepatitis indistinguishable from virally induced disease.

Physical examination will vary depending on the nature of the underlying pathology. The liver can be enlarged and tender. A rash frequently is seen in halothane-induced hepatitis, consistent with its presumed allergic causation. Aminotransferase levels commonly are elevated but only mildly so in cholestatic cases. Bilirubin often is elevated, most dramatically in cases associated with cholestasis. Eosinophilia is a frequent finding in cases of chlorpromazine- or halothane-induced injury.

It can be difficult to differentiate drug-induced liver injury from infectious causes or extrahepatic biliary obstruction. A careful history in conjunction with knowledge of the drugs commonly associated with hepatic toxicity should facilitate diagnosis (Table 88-4). On occasion, particularly in cases with a cholestatic presentation, abdominal ultrasound imaging and liver biopsy may be necessary.

**Management.** The offending agent(s) should be discontinued and appropriate supportive measures instituted, as in the treatment of acute hepatitis. For patients with cholestasis and significant pruritus, a bile acid–sequestering agent such as cholestyramine may provide relief. If an allergic mechanism is suspected, corticosteroids may be of benefit. Although drug-induced liver disease generally is a benign disorder, it can be associated with fulminant hepatic failure or the development of cirrhosis.

**Disposition.** Mild cases of drug-induced hepatitis can be managed effectively on an outpatient basis. Telephone consultation with a gastroenterology specialist is recommended to aid in the diagnosis and ensure reliable follow-up. In severe cases, the patient should be hospitalized, and if signs of fulminant hepatitis are apparent, consideration should be given to transfer to a treatment center with the capacity to perform liver transplantation.

### HEPATIC ABSCESSSES

Hepatic abscesses fall into two broad categories, pyogenic and amebic. Although there may be similarities in clinical presentation, the pathophysiology and treatment differ significantly.
Pyogenic Abscess

**Principles of Disease.** Pyogenic hepatic abscess is uncommon, being reported in only 8 to 16 cases per 100,000 hospital admissions. The disorder increases in frequency with patient age and is distributed equally between men and women. Liver abscesses are most commonly associated with biliary tract obstruction or cholangitis but also may be related to diverticulitis, pancreatic abscess, omphalitis, appendicitis, inflammatory bowel disease, or bacteremia of any cause. In a significant number of cases, no underlying cause for liver abscess is identified.

Solitary and multiple abscesses occur with approximately equal frequency, most often in the right lobe of the liver. Patients with multiple lesions tend to be more severely ill, with less favorable outcomes. Both anaerobic and aerobic organisms are causative; *E. coli*, *Klebsiella*, *Pseudomonas*, and *Enterococcus* species; anaerobic streptococci; and various *Bacteroides* species are the microbes most commonly isolated.

**Clinical Features.** Clinical presentation is characterized by the onset of high fever, chills, right upper quadrant pain, nausea, and vomiting. Patients generally present acutely and appear quite ill, particularly if there is underlying cholangitis. A more insidious chronic presentation, although atypical, has been described. Physical findings include elevated temperature, right upper quadrant tenderness, hepatomegaly, and occasionally dullness to percussion and decreased breath sounds over the right lower chest. Jaundice may be apparent, especially if coexistent biliary tract obstruction is present.

**Diagnostic Strategies.** Laboratory findings include leukocytosis in 70 to 80% of cases, elevated alkaline phosphatase in up to 90%, and bilirubin in excess of 2 mg/dL in 50% of patients. Serum aminotransferase levels commonly are elevated to two to four times normal. Chest radiographs may reveal a right pleural effusion, basilar atelectasis, or an elevated right hemidiaphragm.

Many imaging techniques are useful in delineating hepatic abscesses, including ultrasonography, CT scan (Figs. 88-4 and 88-5), and magnetic resonance imaging (MRI). In the ED, ultrasonography and CT scan are the most sensitive and expeditious modalities.

**Differential Considerations.** The differential diagnosis of pyogenic hepatic abscess includes amebic liver abscess, hepatitis, and cholangitis, as well as pancreatic and subphrenic abscess. Although clinical evaluation may not allow definitive diagnosis, appropriate use of imaging techniques generally does.

**Management.** The initial treatment of a pyogenic hepatic abscess is hemodynamic stabilization, intravenous antibiotics, and pain control. Pending definitive microbial identification, broad-spectrum antibiotic coverage should be provided. Triple antibiotic coverage is warranted and should include an aminoglycoside or third-generation cephalosporin for gram-negative coverage, metronidazole or clindamycin for anaerobes, and ampicillin for streptococcal species.

Definitive treatment requires abscess drainage. This usually is done percutaneously, with open surgical drainage reserved for complex cases associated with intraperitoneal soiling, intestinal perforation, or biliary obstruction. Complications include rupture of the abscess into the peritoneal cavity or an adjacent anatomic structure (e.g., the thoracic cavity, lung, pericardium).

**Disposition.** Patients with pyogenic hepatic abscess uniformly require admission to the hospital. Consultation with a general surgeon, gastroenterologist, or interventional radiologist will be necessary.

Amebic Abscess

**Principles of Disease.** Amebiasis is one of the most common protozoal infections worldwide. Up to 10% of the world’s population and approximately 1 to 2% of the U.S. population may be infected. Transmission generally occurs by way of the fecal-or oral route and usually is a consequence of ingesting contaminated water or foodstuffs. The illness is more common in homosexual men, presumably as a result of oral-anal contact during sexual activity. One limited but fatal outbreak of intestinal disease in the Midwest was traced to a contaminated colonic irrigation apparatus. Although intestinal disease is by far the most common manifestation of infection, extraintestinal disease is not rare, with the liver most commonly affected. *Entamoeba histolytica* is the only ameba responsible for invasive disease, and evidently only certain varieties of *E. histolytica* are pathogenic. Pathogenic amoebae reach the liver after invasion of the intestinal mucosa and transit through the portal vein. As with a pyogenic abscess, involvement of the right liver lobe is more common.

---

**Figure 88-4.** Contrast computed tomography scan of liver showing large cystic masses (black arrow, white arrow) with irregular, contrast-enhancing borders in a patient with pyogenic liver abscess caused by *Streptococcus milleri*.

**Figure 88-5.** Contrast computed tomography scan of liver showing pyogenic liver abscess. Complex cystic mass with air-fluid level (arrow) caused by gas-producing *Klebsiella pneumoniae*. 
Clinical Features. The clinical presentation generally is acute, with fever, chills, abdominal pain, nausea, and vomiting. Diarrhea is common in children but is present in less than one third of adults. Careful questioning of patients without diarrhea often yields a history of intestinal illness several weeks before. Many patients complain of cough, which can serve to direct attention away from the liver.

Chronic illness of several months’ duration, although less common than the acute presentation, has been described. Physical examination reveals an elevated temperature, right upper quadrant tenderness, hepatomegaly, and dullness with decreased breath sounds over the right lower chest.

Diagnostic Strategies. Laboratory parameters are not specific. Neutrophilic leukocytosis is common. Alkaline phosphatase is elevated in 75% of cases and aminotransferases in 50%. Hyperbilirubinemia is uncommon and when present is indicative of biliary obstruction. The chest radiograph may reveal a right pleural effusion, basilar atelectasis, or an elevated right hemidiaphragm. Ultrasound imaging of the liver can be diagnostic, revealing a peripherally based mass with well-circumscribed borders and a heterogenous hypoechoic center. Nuclear scintigraphy with technetium, CT scan, and MRI are alternative imaging modalities if ultrasonography is inconclusive.

Diagnosis is supported by identification of a pathogenic protozoan in the stool. Even in cases of invasive intestinal disease, however, the yield may be low. An enzyme-linked immunosorbent assay (ELISA) or a counterimmune electrophoresis generally is preferred. The indirect hemagglutination test remains positive for an extended period and is therefore not helpful in establishing the presence of acute infection.

Differential Considerations. In a review of 75 cases of amebic liver abscess seen in a single ED over 5 years, the correct diagnosis was made in the ED in only 31.5% of patients. In order of their frequency of occurrence, considerations in the differential diagnosis of an amebic liver abscess include pyogenic abscess, biliary tract disease, hepatitis, pneumonia, appendicitis, and pancreatitis. Respiratory symptoms and abnormalities on the chest radiograph may cause confusion with pulmonary illnesses. Hepatic imaging is helpful in establishing the correct diagnosis; however, differentiation from pyogenic illness may still be difficult.

Management. Management consists of supportive therapy and initiation of amebicidal therapy. Metronidazole, 750 mg PO or IV three times daily for 7 days, is the therapeutic agent of choice. Most patients will respond to this regimen. Percutaneous catheter drainage is required only in refractory or complicated cases.

The most serious complication of amebic liver disease is rupture into adjacent anatomical structures. Involvement of the lung occurs in 20 to 35% of cases of extrahepatic disease, often manifesting with signs and symptoms of massive pleural effusion or consolidative pneumonia. With rupture into a bronchus, the patient can present with cough productive of an anchovy paste–like substance or necrotic debris, or with frank hemoptysis. Abdominal pain with peritonitis can result from rupture into the abdominal cavity. Involvement of the pericardium occasionally is seen with lesions in the left lobe of the liver and can be catastrophic, either acutely as a consequence of pericardial tamponade or chronically from constrictional pericarditis.

Disposition. Select patients with amebic liver abscess can be managed as outpatients. This approach is best suited for persons with mild clinical disease, stable living circumstances, and adequate access to medications as well as follow-up care. Patients with more severe disease, evidence of complications, or questionable social circumstances should be admitted to a medical service.
coagulation (prolonged PT and partial thromboplastin time, hypofibrinogenemia, elevated fibrin split products, and thrombocytopenia). Treatment involves aggressive fluid and electrolyte support, glucose administration, and immediate delivery. Liver disease generally resolves without permanent sequelae after delivery.106

Budd-Chiari Syndrome

Budd-Chiari syndrome is a disorder of the liver due to hepatic venous outflow obstruction located anywhere above the level of hepatic venules. It is an uncommon disorder with a prevalence of 1/100,000 worldwide and is more common in females. The disorder is associated with hypercoagulable states such as factor V Leiden, protein S and C deficiency, thrombophilia, antithrombin III deficiency, myeloproliferative disorder, Behçet’s disease, paroxysmal nocturnal hemoglobinuria, and oral contraceptive use.101,102 In Asia, an association with a membranous obstruction of the inferior vena cava has been reported.102

Clinical presentation is variable, ranging from fulminant hepatic failure in acute high-grade obstruction to the insidious onset of jaundice and ascites in more subacute forms. Fulminant disease is clinically indistinguishable from acute hepatic necrosis from hepatocellular disease secondary to viral infection. It is important to make the distinction between these two causes of hepatic failure early, because treatment options differ. Prompt intervention in patients with Budd-Chiari syndrome offers the possibility of effective relief of signs and symptoms with potentially favorable outcome.

Doppler ultrasound imaging is reported to have sensitivity between 85% and 95% for diagnosis of Budd-Chiari syndrome and emerges as the diagnostic modality of choice in the ED setting.101,103,104

Management of Budd-Chiari syndrome relates to the severity and acuity of disease. Previously diagnosed disease with worsening ascites can be managed with modification of diuretics and therapeutic paracentesis followed by referral to a primary care physician or gastroenterology specialist. Newly diagnosed Budd-Chiari syndrome with acute decompensation will require immediate consultation and consideration for transjugular intrahepatic portosystemic shunt placement or percutaneous angioplasty or thrombolytic therapy. Portacaval shunting and liver transplantation are options for disease refractory to medical or other less invasive percutaneous interventions.101,105,106

Hepatic Cancer

Hepatocellular carcinoma is the most common primary hepatic malignancy. It is especially common in undeveloped areas of the world, particularly in regions in which chronic HBV infection is prevalent. In parts of Korea and Mongolia, the incidence of hepatocellular carcinoma approaches 48 to 98 per 100,000 population; in the United States, it is below 10 per 100,000.107 It has been estimated that 75 to 80% of primary liver cancer is attributable to persistent viral infections with either HBV (50 to 55%) or HCV (25 to 30%).107 Associations beyond HBV include infection with Clonorchis and schistosomiasis, chronic alcoholic liver disease, primary biliary cirrhosis, hemochromatosis, and several chemical agents (e.g., estrogens, androgens, the contrast agent Thorotrast, vinyl chloride, aflatoxins, tobacco).108 Metastases to the liver from GI, lung, breast, or other tumors are more common than primary malignancy in the United States.

The clinical presentation of hepatic carcinoma or metastases is nonspecific. Symptoms and signs may include nausea, vomiting, jaundice, and right upper quadrant abdominal pain. Physical examination may reveal evidence of recent weight loss or cachexia. Hepatocellular carcinoma is linked with cirrhosis; many of these patients present with manifestations of that process. An enlarged liver, particularly in patients with a history of cirrhosis, is strongly suggestive of malignant transformation. Although results of laboratory tests (e.g., blood count, aminotransferase measurements, bilirubin assay) often are abnormal, these tests are nonspecific and generally are of little aid in diagnosis. Alpha-fetoprotein often is elevated in patients with a hepatoma but is nonspecific and of limited use in diagnosis. Ultrasound imaging, CT scan, and MRI of the liver all are effective means of identifying tumor. Liver biopsy is recommended for the definitive diagnosis of hepatoma; biopsy of an alternative site may be preferable in cases of metastatic disease.

Management in the ED is limited to supportive measures, provision of analgesic agents, and possibly nutritive supplementation. Hepatitis B and C serologic studies should be performed in cases of hepatoma to determine linkage with chronic HBV infection and to assess infection risk to family members.

Liver Transplantation

Human orthotopic liver transplantation was pioneered in the 1960s, and approximately 5000 liver transplant procedures are now performed annually in the United States. The 5-year survival rate generally is reported to be approximately 80%, but complications are common.109,110 Early complications include bleeding, acute rejection, vascular and biliary tract problems, and infection. Delayed complications include malignancy, recurrence of underlying disease, infection, chronic rejection, medication toxicity, and renal failure. Many early complications will manifest during the initial postoperative period while the patient is in the hospital or being closely followed by the transplantation team. Delayed complications may occur a year or more after transplantation.

The clinical signs that lead the transplant recipient to present for care in the ED are related to the nature of the underlying problem. The signs of malignancy or recurrence of underlying disease will mirror those in the patient who has not undergone transplantation. Infectious complications will be relatively straightforward when common pyogenic organisms are involved; however, liver transplant recipients are at increased risk for opportunistic infections as a consequence of their immunosuppressive therapy. Presenting signs and symptoms may be subtle. Chronic rejection manifests with low-grade temperature elevation, fatigue, and jaundice. Expected laboratory abnormalities include elevated bilirubin and transaminases, prolonged PT or INR, and low serum albumin. Renal failure may not be clinically apparent until the glomerular filtration rate has declined significantly. Routine serum creatinine measurement is the best means of identifying this disorder early, when successful intervention is still possible.

The most common immunosuppressive agents used after liver transplantation include corticosteroids, cyclosporine, tacrolimus, sirolimus, mycophenolate, and azathioprine. Corticosteroid toxicity may produce glucose intolerance, osteoporosis, gastric ulceration, and muscle wasting. Cyclosporine and tacrolimus can cause renal impairment, which is the most common dose-limiting effect of these agents. Azathioprine can be hepatotoxic but is more often associated with bone marrow suppression, placing the patient at increased risk for infectious complications and bleeding diathesis.

Management of patients with complications related to their liver transplant is directed by the nature of the problem. Infec-
tions are evaluated and managed in the usual fashion, with emphasis on evaluation of the patient's underlying immune function and a search for uncommon pathogens. Accordingly, assessment may include complete blood count and measurement of glucose, blood urea nitrogen, creatinine, serum electrolytes, transaminases, bilirubin, and albumin, as well as coagulation studies. Hepatobiliary imaging is indicated if tumor, vascular occlusion, or biliary tract obstruction is suspected. Ultrasound studies with Doppler interrogation can be particularly useful in the ED setting. Consultation with a transplantation specialist is recommended for any patient with a problem potentially related to the organ transplant or immune-modulating medications.

**BILIARY TRACT DISORDERS**

**GENERAL PERSPECTIVE**

The biliary tract is composed of the hepatic bile canaliculi, intrahepatic and extrahepatic bile ducts, the common bile duct, and the gallbladder. Bile, required for absorption of fats and fat-soluble nutrients, is produced in the canaliculi. During the fasting state, approximately 50% of the bile produced flows directly into the duodenum; the other half is stored in the gallbladder. The gallbladder serves to acidify and concentrate the bile and can store up to 50 mL of bile for immediate availability at the time of feeding. The presence of food in the stomach, in particular fat, results in both vagal impulses and the secretion of cholecystokinin-pancreozymin, which serve as potent stimuli for gallbladder contraction. Removal of the gallbladder generally is not associated with measurable changes in intestinal fat absorption or in clinical symptomatology.111

Biliary tract disorders constitute a relatively common cause of presentation to the ED. Signs and symptoms typically result from obstruction of the biliary tree. The clinical picture is variable but often includes abdominal pain, which may or may not be referred; nausea and vomiting; and jaundice.

**SPECIFIC DISORDERS**

**Cholelithiasis**

As noted, the principal cause of biliary tract disease is related to the development of gallstones. It is estimated that 20% of women and 8% of men have gallstones, resulting in approximately 500,000 operations annually.112

**Principles of Disease.** There are two categories of gallstones. **Cholesterol stones** most commonly occur as a consequence of an elevated concentration of cholesterol in bile relative to the other principal constituents, bile acids and phospholipids. Bile acids and lecithin, the primary bile phospholipid, act in concert to solubilize cholesterol. As cholesterol levels rise or bile acids and lecithin levels decline, cholesterol has an increasing tendency to form crystals. These crystals, particularly in an incompletely emptying gallbladder, serve as a nidus for stone formation. Factors associated with an enhanced risk of cholesterol stone formation include increased age, female gender, massive obesity, rapid weight loss, cystic fibrosis, parity, drugs (e.g., clofibrate, oral contraceptive agents), and familial tendency. The hereditary nature of cholelithiasis is most dramatically demonstrated by the high concordance for stone formation in monozygotic twins and the exceedingly high incidence of cholelithiasis among Pima Indians.113

Two varieties of **pigmented stones** have been identified: black and brown. Black stones occur exclusively in the gallbladder and contain a high concentration of calcium bilirubinate. They are more commonly encountered in elderly persons and have a strong association with disease causing intravascular hemo-

lysis (e.g., sickle cell anemia, hereditary spherocytosis). Brown stones are associated with infection and can form in both the gallbladder and the intrahepatic and extrahepatic bile duct system. Although bacterial infections are most commonly incriminated, parasites (e.g., *Ascaris lumbricoides*, *Clonorchis sinensis*) also been linked to brown stone formation.114 Both types of pigmented stones contain calcium bilirubinate and therefore may be visible on plain abdominal radiographs. For a stone to be radiopaque, it must contain at least 4% calcium by weight.

**Clinical Features.** The most common clinical manifestation of cholelithiasis is biliary colic. The pathophysiology of this process is not entirely clear, but it appears to be related to the passage of small stones from the gallbladder through the cystic duct into the common bile duct. The term **colic** is often misleading; affected patients commonly complain of steady pain, rather than intermittent or cramping discomfort. The pain most often is perceived in the right upper quadrant but may be localized over a wide region of the upper abdomen. Radiation of pain, if it occurs, generally is to the base of the scapula or shoulder. Associated signs and symptoms include nausea and vomiting, which may be severe enough to lead to fluid and electrolyte imbalance. Patients with biliary colic commonly report similar self-limited occurrences in the past and may offer an association between symptom onset and eating. A relationship between fatty food ingestion and symptoms is as likely to occur in patients with gallstones as it is in those without. Physical examination usually reveals mild tenderness to palpation without guarding or rebound in the right upper quadrant or epigastric region.

**Diagnostic Strategies.** No pathognomonic clinical laboratory findings are recognized; results of commonly performed tests typically are within normal limits. Important tests to perform include ALT and AST measurements to evaluate for the presence of hepatitis, bilirubin and alkaline phosphatase determinations to look for evidence of common duct obstruction, and lipase assay to assess for the presence of pancreatitis.

The diagnosis of biliary colic is made clinically in conjunction with demonstration of stones in the gallbladder. Plain radiography has little role in the evaluation of cholelithiasis because only 10% of stones have sufficient calcium to allow visualization.115 Ultrasonography is the procedure of choice for investigating the gallbladder. Ultrasound imaging can be performed rapidly, is highly sensitive, and provides the added utility of permitting evaluation of surrounding structures (Fig. 88-6). Ultrasonography also can be used in the ED setting, adding further convenience to the patient and reducing turnaround times.116 Oral cholecystography using ipanoic acid is an alternative when ultrasonography either is not available or cannot be performed successfully. This technique can identify gallstones in 95% of patients with cholelithiasis in whom visualization of the gallbladder can be achieved.

**Differential Considerations.** Considerations in the differential diagnosis of biliary colic include cholecystitis, peptic acid disease of the stomach or duodenum, pancreatitis, and hepatitis. Patients with cholelithiasis may occasionally present with chest pain, so cardiopulmonary syndromes must be considered as well. A compatible clinical history in conjunction with normal laboratory test values (ALT, AST, lipase, and alkaline phosphatase), gallstones on ultrasound imaging, and minimal or no tenderness in the right upper quadrant favors the diagnosis of cholelithiasis. If abnormalities are visualized, a chest radiograph or electrocardiogram may help differentiate between cardiopulmonary and biliary pathology.

**Management.** The initial management of biliary colic is directed at correction of fluid and electrolyte disturbances and
Obstruction of the cystic duct appears to Considerations. Biliary colic is an uncommon symptom in A polymorphonuclear leukocytosis Features. PART III ■ Medicine and Surgery SeCtion Five • Gastrointestinal System 1168 parturition. ED is comparable with that for the nonpregnant patient; considerable diagnostic use in this setting. Treatment in the later pregnancy, which alters anatomic relationships and interferes with abdominal examination. Ultrasound imaging is of common occurrence of nausea and vomiting, particularly in children, in whom it most often is associated with an underlying hemolytic disorder (e.g., sickle cell anemia or spherocto-
sis). Acute management of biliary colic is the same for children as for adults.

The most common complication of biliary colic is fluid and electrolyte imbalance secondary to vomiting. Other adverse consequences include Mallory-Weiss tear, from uncontrolled emesis, and cholangitis, from unrecognized and persistent common bile duct obstruction.

Special Considerations. Biliary colic is an uncommon symptom in children, in whom it most often is associated with an underlying hemolytic disorder (e.g., sickle cell anemia or spheroctosis). Acute management of biliary colic is the same for children as for adults.

Cholelithiasis may be encountered in pregnant women. Diagnosis in this population is made more difficult by the common occurrence of nausea and vomiting, particularly in the first trimester, and the presence of an enlarged uterus in later pregnancy, which alters anatomic relationships and interferes with abdominal examination. Ultrasound imaging is of considerable diagnostic use in this setting. Treatment in the ED is comparable with that for the nonpregnant patient; however, definitive therapy generally is delayed until after parturition.

Figure 88-6. Gallbladder with gallstones (Stones), thickened gallbladder wall (GBW), and pericholecystic fluid (FF). Together these findings constitute the sonographic signs of cholecystitis.

relief of symptoms. Vomiting is managed with antiemetics and, if necessary, nasogastric suction. Pain often can be controlled with antispasmodics (e.g., glycopyrrolate), nonsteroidal anti-inflammatory agents, and opiate analgesic agents as needed. With clinical evidence of volume depletion, adequate intravenous fluid replacement is indicated.

The definitive management of cholelithiasis usually involves surgical removal of the gallbladder; however, other options are available. Oral administration of bile acid (e.g., chenodeoxycholate, ursodeoxycholate) over a period of months to years can result in dissolution of small to medium-size stones, whereas methyltert-butyl ether irrigation of the gallbladder has shown to dissolve stones over a period of hours or days. Extracorporeal shock wave lithotripsy may be successful in a select, technically suitable set of patients who have functioning gallbladders and ideally have a small number of stones.

The most common complication of biliary colic is fluid and electrolyte imbalance secondary to vomiting. Other adverse consequences include Mallory-Weiss tear, from uncontrolled emesis, and cholangitis, from unrecognized and persistent common bile duct obstruction.

Special Considerations. Biliary colic is an uncommon symptom in children, in whom it most often is associated with an underlying hemolytic disorder (e.g., sickle cell anemia or spheroctosis). Acute management of biliary colic is the same for children as for adults.

Cholelithiasis may be encountered in pregnant women. Diagnosis in this population is made more difficult by the common occurrence of nausea and vomiting, particularly in the first trimester, and the presence of an enlarged uterus in later pregnancy, which alters anatomic relationships and interferes with abdominal examination. Ultrasound imaging is of considerable diagnostic use in this setting. Treatment in the ED is comparable with that for the nonpregnant patient; however, definitive therapy generally is delayed until after parturition.

Cholecystitis

Perspective. Acute cholecystitis is defined as sudden inflammation of the gallbladder. The incidence ranges from 5 to 19% among patients undergoing surgery for biliary tract disorders. The risk factors for cholecystitis are similar to those for cholelithiasis: female gender, increasing age and parity, and obesity. Although gallstones play a prominent role in the pathogenesis of cholecystitis, approximately 2 to 12% of cases are categorized as acalculous.

Principles of Disease. Obstruction of the cystic duct appears to be the critical factor in the development of gallbladder inflammation. Gallstones are identified in 95% of patients with cholecystitis and may be located in the common bile duct in many patients with acalculous cholecystitis. Causes of cystic duct obstruction unrelated to stone disease include tumor, lymphadenopathy, fibrosis, parasites, and kinking of the duct. Regardless of cause, obstruction of the cystic duct leads to filling and distention of the gallbladder. The ensuing inflammatory reaction may be related to mucosal ischemia from increased hydrostatic pressure or to the action of cytotoxic products of bile metabolism (e.g., lysophosphatidylcholine). Although bacteria are isolated from the bile of inflamed gallbladders in a majority of cases, the role of infection in the pathogenesis of cholecystitis is not completely understood. Coliforms (e.g., E. coli) represent the most common isolates, but anaerobes have been identified in as many as 40% of cases.

Clinical Features. The most common presenting symptom of cholecystitis is pain, usually in the right upper quadrant. Although the pain initially may be described as colicky, it will become constant in virtually all cases. A previous history of similar but less severe and self-limited symptoms is a valuable diagnostic clue, as is documentation of previous gallstones. Radiation of pain generally is to the tip of the scapula on the right. Nausea and vomiting are typical features, and the patient may exhibit fever.

Physical examination reveals tenderness in the right upper quadrant or epigastric region, often with guarding or rebound. Murphy’s sign (tenderness and an inspiratory pause elicited by palpation of the right upper quadrant during a deep breath) is compatible with, but not specific for, gallbladder inflammation. Fever and tachycardia are commonly absent, so cholecystitis should remain a diagnostic consideration in the absence of these findings in patients with abdominal pain and right upper quadrant pain and tenderness to palpation.

Diagnostic Considerations. A polymorphonuclear leukocytosis with left shift is common, but the WBC count has been reported to be in a normal range in 27 to 40% of patients. Serum aminotransferase, bilirubin, and alkaline phosphatase may be mildly elevated but more often are within normal limits. An elevated lipase should suggest the diagnosis of pancreatitis, either instead of or in addition to cholecystitis. Plain abdominal radiographs may reveal calcified stones, gas in the gallbladder, or an upper quadrant sentinel loop. These findings are so uncommon and nonspecific, however, that plain radiography is not recommended unless other diagnostic considerations are present.

Ultrasound imaging is the most useful test in the ED setting. Visualization of the gallbladder without identification of stones has an extremely high negative predictive value for cholecystitis, whereas the presence of stones, a thickened gallbladder wall, and pericholecystic fluid has a positive predictive value in excess of 90% (Fig. 88-7).

Nuclear scintigraphy with technetium 99m–labeled imino-diaceitic acid (IDA) generally is considered the most sensitive and specific imaging test for cholecystitis. IDA administered IV is taken up by hepatocytes and secreted into the bile canaliculi. Failure to obtain an outline of the gallbladder within 1 hour of administration of IDA in the face of hepatic and
common duct visualization proves cystic duct obstruction. In the appropriate clinical setting, this finding is diagnostic of cholecystitis. Conversely, visualization of the gallbladder and common duct within 1 hour of administration has a negative predictive value of 98%. Scintigraphy with IDA loses its sensitivity as serum bilirubin rises above 5 to 8 mg; however, scintigraphy with diisopropyl IDA (diisopropyl iminodiacetic acid, or mebrofenin) allows visualization of the biliary tree in patients with total serum bilirubin in the range of 20 to 30 mg. Although not the preferred imaging modality, CT can identify patients with total serum bilirubin in the range of 20 to 30 mg. Although not the preferred imaging modality, CT can identify patients with total serum bilirubin in the range of 20 to 30 mg.

Differential Considerations. Diagnostic considerations in the patient suspected of having cholecystitis include hepatitis, hepatic abscess, pyelonephritis, right lower lobe pneumonia or pleurisy, pancreatitis, peptic acid disease of the duodenum, and appendicitis. Up to 20% of patients with acute cholecystitis may be misdiagnosed when only clinical criteria are considered. Accurate diagnosis often requires the use of sonographic or, less commonly, scintigraphic or CT studies.

Management. Basic supportive measures provide the foundation for initial management of acute cholecystitis. Volume status should be optimized with intravenous crystalloid administration. Emesis can be managed with antiemetics and nasogastric suction. Nasogastric suctioning may have the added benefit of diminishing the stimulus for biliary secretion and excretion, thereby adding to pain relief. Narcotic analgesic agents are useful for pain control. Despite the questionable role of microbial infection in the pathogenesis of cholecystitis, antibiotics are recommended. Unless clinical evidence of sepsis exists, coverage with a single broad-spectrum antibiotic (e.g., a second- or third-generation cephalosporin) is adequate.

The most serious complication of cholecystitis is gangrene of the gallbladder, with necrosis and perforation. Localized perforation may lead to pericholecystic abscess or fistula formation, the latter predisposing to gallstone ileus at a later date. Patients with diabetes mellitus are at increased risk for bacterial invasion of the gallbladder wall and for the development of emphysematous cholecystitis.

Disposition. Hospitalization for antibiotic therapy and pain management is required. Surgery is recommended for patients with cholecystitis; however, the best timing for operation is not certain. Surgery usually is performed after symptoms have subsided but while the patient is still hospitalized. Immediate cholecystectomy or cholecystotomy is reserved for the complicated case in which the patient has gangrene or perforation.

Special Considerations. Cholecystitis is uncommon in the pediatric age group; when it occurs, however, pediatric cholecystitis should be managed as in the adult. Cholecystitis in the pregnant woman poses challenges in both diagnosis and therapy. Initial therapy is identical to that for the nonpregnant patient, but the issue of surgical intervention requires an individualized consultation between surgeon and obstetrician.

Acalculous cholecystitis occurs in approximately 7 to 9% of cases. It is more common in elderly persons and most often is encountered in patients who are recovering from non–biliary tract surgery. Over the past decade, acalculous disease has been increasingly encountered as a complication of advanced AIDS, usually secondary to infection with cytomegalovirus (CMV) or Cryptosporidium. In comparison with calculous disease, acalculous cholecystitis tends to have a more acute and malignant course, with a mortality rate as high as 41%. The same techniques are used to diagnose acalculous disease as in other forms of cholecystitis but are less sensitive and specific for this entity. Sonographic findings include thickening of the gallbladder wall, pericholecystic fluid, and lack of response to cholecystokinin. Scintigraphic findings are the same as in calculous disease.

Emphysematous cholecystitis is an uncommon variant of cholecystitis, occurring in approximately 1% of cases. It is characterized by the presence of gas in the gallbladder wall, presumably consequent to the invasion of the mucosa by gas-producing organisms (e.g., E. coli, Klebsiella species, Clostridium perfringens). It is more common in diabetic patients, has a male predominance, and is acalculous in up to 50% of cases. Clinical presentation and physical findings are similar to those in cholecystitis. Plain radiographs or CT scans of the abdomen will reveal gas in the gallbladder wall. Because of a high incidence of gangrene and perforation, emergency cholecystectomy is recommended. Antibiotic coverage should include penicillin, an aminoglycoside, and clindamycin or an ampicillin-sulbactam combination agent. The mortality rate for emphysematous cholecystitis is approximately 15%.
Cholangitis

**Perspective.** Acute obstructive cholangitis was first described by Charcot in 1877. In one large series, it was reported to occur in approximately 8% of patients admitted for biliary tract disease. Cholangitis most often is a consequence of common duct blockage by a gallstone but may be associated with malignancy or a benign stricture.

**Principles of Disease.** The key factors in the pathogenesis of cholangitis are obstruction, elevated intraluminal pressure, and bacterial infection. Incomplete obstruction occurs more commonly than complete blockage. Bacteria may gain access to the obstructed common duct either in a retrograde manner from the duodenum, by way of the lymphatics, or from portal vein blood. The most commonly encountered organisms are similar to those encountered in other varieties of biliary tract disease: *E. coli* and *Klebsiella, Enterococcus,* and *Bacteroides.*

**Clinical Features.** Patients most often experience fever, chills, nausea, vomiting, and abdominal pain. The classic triad of physical findings first described by Charcot consists of right upper quadrant pain, fever, and jaundice. Although these findings are compatible with cholangitis, they also can be seen with both cholecystitis and hepatitis. Sepsis is a common complication and may be heralded by tachycardia, tachypnea, and frank hypotension. The presence of Charcot’s triad along with the clinical signs of sepsis—hypotension and altered sensorium—is referred to as Reynold’s pentad.

**Diagnostic Considerations.** Common laboratory abnormalities include polymorphonuclear leukocytosis, hyperbilirubinemia, elevated alkaline phosphatase, and moderately increased amylase and lipase. Arterial blood gas (ABG) measurements are useful to identify base deficit as an early sign of sepsis. Sonography can be helpful if it demonstrates common and intrahepatic ductal dilatation, whereas identification of stones in the gallbladder or common duct suggests the underlying cause of obstruction (see Fig. 88-7). Although nuclear scintigraphy cannot determine the cause, it appears to be a more sensitive means to diagnose early obstruction. Several studies have demonstrated a high incidence of nonvisualization of the biliary tree with cholescintigraphy in patients with common duct obstruction when sonography failed to identify dilatation.

Alternative imaging techniques include CT scan, percutaneous transhepatic choledangiography (THC), and endoscopic retrograde cholangiopancreatography (ERCP). Although these techniques may be more expensive and time-consuming, the latter two have the added benefit of offering potential therapeutic benefit. Endoscopic cholangioscopy can permit culture of bile, direct removal of obstructing stones, or decompression of the biliary tree by sphincterotomy or stent placement.

**Differential Considerations.** Although patients with cholangitis generally have a higher fever and appear more ill than those with cholecystitis, considerable variability and overlap are possible. The presence of jaundice is the clinical sign most helpful in differentiating between these two disorders. An elevated bilirubin is characteristic of cholangitis and uncommon in cholecystitis. Ultrasonographic evidence of dilated common and intrahepatic ducts usually is required to distinguish cholangitis from cholecystitis.

**Management.** Treatment of cholangitis includes hemodynamic stabilization with crystalloid fluid and, if necessary, vasopressors. Broad-spectrum antibiotic coverage should be initiated immediately after blood culture specimens are obtained. The choice of antibiotics should be guided by local sensitivities and must provide coverage for enteric microbes. Single-agent therapies include piperacillin plus tazobactam, mezlocillin, imipenem, meropenem, ticarcillin plus clavulanate, and ampicillin plus sulbactam (which may be combined with metronidazole). Combination therapy includes a regimen of extended-spectrum cephalosporin, metronidazole, and ampicillin. The key to successful treatment is early biliary tract decompression. This can be achieved with THC, ERCP, or surgery.

**Disposition.** Patients with cholangitis will require hospitalization, preferably to a monitored setting. Prompt consultation with a service that can provide for biliary tract decompression (surgery, interventional radiology, or gastroenterology) is necessary.

**Sclerosing Cholangitis**

Sclerosing cholangitis is an idiopathic inflammatory disorder affecting the biliary tree. It is characterized by diffuse fibrosis and narrowing of the intrahepatic and extrahepatic bile ducts. It is commonly associated with inflammatory bowel disease, particularly ulcerative colitis; however, in 25% of cases, it appears as an isolated disorder.

Patients usually present with complaints of weight loss, lethargy, jaundice, and pruritus. Rarely, infective cholangitis may develop. Prompt diagnosis may be more difficult in these cases because of the sclerotic nature of the bile ducts and the absence of duct dilatation on ultrasound imaging. Surgical exploration or ERCP often is required for diagnosis. The management of noninfected cases is primarily symptomatic. Cholestyramine, a bile acid sequestrant, may diminish pruritus.

**AIDS Cholangiopathy**

Manifestations of advanced HIV disease, generally associated with CD4+ counts less than 200/mm3, may include any one of a group of disorders collectively referred to as AIDS cholangiopathy. These disorders include bile duct strictures, papillary stenosis, and sclerosing cholangitis. The precise pathophysiology is not completely understood but is related to infection with either CMV, Cryptosporidium, microsporidia, or Mycobac-
**terium avium** complex. Clinical presentation may be similar to that in other causes of cholangitis, with fever and right upper quadrant pain. Laboratory test results include increased levels of alkaline phosphatase and minor elevation of transaminases. Bilirubin is less commonly elevated than in other disorders causing cholangitis. Ultrasonography generally is helpful in identifying bile duct stricture, thickening, or dilatation. IDA scans are useful, as they are in other causes of cholangitis. Management involves endoscopic sphincterotomy or stent placement in conjunction with treatment of the underlying infection.

**Porcelain Gallbladder**

The porcelain gallbladder is a dramatic radiographic finding caused by either linear or punctate calcifications within the gallbladder wall. Most patients are women, with a mean age in the 50s. Gallstones are commonly present. The gallbladder may be palpable in the right upper quadrant and is usually nontender to palpation. Patients with this disorder should be referred for cholecystectomy because of the high incidence of associated carcinoma.

**Malignancy**

Carcinoma of the biliary tract is uncommon. Gallbladder carcinoma is the most common malignancy of the biliary tract, accounting for 5% of all cancers found at autopsy. Gallbladder cancer is more frequent in patients with gallstones, especially if the gallstones are symptomatic and large. Other factors associated with gallbladder cancer include female gender, obesity, and high carbohydrate intake, all associated with gallstone disease. Metastatic disease to regional nodes and the liver is common at the time of initial diagnosis because of the relatively silent nature of early disease. Symptoms include chronic right upper quadrant pain and jaundice. Physical examination may reveal a palpable mass in the right upper quadrant. These tumors will occasionally perforate, and the patient may have symptoms of pericholecystic abscess. Non-invasive imaging techniques may be of some aid in identifying the tumor. Ultrasound imaging is more sensitive than CT, but even the sequential use of both tests fails to identify malignancy in 49% of cases.

Carcinoma of the extrahepatic bile ducts is less frequent than gallbladder malignancy and is more common in men. Jaundice is the most frequent finding. A palpable gallbladder (Courvoisier’s sign) may be present on physical examination in one third of cases. The diagnosis is suggested by the presence of dilated intrahepatic and extrahepatic bile ducts on sonography. THC and ERCP may serve to delineate better the location and extent of tumor. Scirrhous carcinomas may have a radiographic appearance similar to that of sclerosing cholangitis, and the two conditions can be effectively differentiated only with surgical biopsy. Both gallbladder and ductal carcinomas carry a similarly dismal prognosis, with 5-year survival rates in the range of 5 to 10%. Carcinoma of Vater’s ampulla is more common in elderly persons and in males. The critical location of the ampulla results in relatively early symptomatology and thus more prompt diagnosis. Ultrasound imaging is the most useful initial imaging technique, but GI endoscopy and ERCP generally are necessary to provide a definitive diagnosis. Early detection contributes to the more favorable prognosis.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
The pancreas is a retroperitoneal organ extending across the posterior abdomen in the epigastrium (Fig. 89-1). The head of the pancreas sits in the loop of the first part of the duodenum, whereas the tail lies against the hilum of the spleen. The main pancreatic duct (duct of Wirsung) goes from the tail through the body, to the head of the pancreas and where the common bile duct enters the second part of the duodenum through the sphincter of Oddi. Accessory ducts and anomalies are not uncommon. Anterior to the pancreas from right to left are the transverse colon, the lesser sac of the omentum, and the stomach. Posteriorly lie the bile duct, portal vein, splenic vein, vena cava, aorta, and superior mesenteric artery. To the left are the psoas muscle, kidney, and adrenal gland. Because of their close proximity, inflammation of the pancreas may not only injure these structures but also can mimic a variety of diseases.

The pancreas has both essential exocrine and endocrine functions. Exocrine products include amylase, lipase, trypsin, chymotrypsin, elastase, carboxypeptidase, phospholipase, and other enzymes. In addition, bicarbonate is produced in greatest quantity from this organ. The bicarbonate serves to neutralize gastric acids as well as the enzymes that break down proteins, carbohydrates, and fats. Cholecystokinin, pancreozymin, and secretin, as well as other factors, control secretion of these enzymes. The endocrine functions of the pancreas are managed by insulin, glucagon, pancreatic polypeptide, and somatostatin.

In the general population, diabetes is the most common disorder of the pancreas, followed by pancreatitis. Acute pancreatitis is an inflammatory process of the pancreas usually associated with abdominal pain, elevated pancreatic enzymes, and variable involvement of other regional tissues or remote organ systems. Both local and systemic complications may occur. Repeated bouts of pancreatitis of any cause may eventually lead to chronic pancreatitis as a result of permanent alterations in function and morphology. Chronic pancreatitis is an ongoing inflammation of the pancreas, which may be interrupted by spells of acute pancreatitis.

Pancreatic tumors may develop from the endocrine or nonendocrine structures. These tumors may cause acute pancreatitis, but usually present in a more indolent fashion. The most common is adenocarcinoma originating from the pancreatic ducts.

The first reports of pancreatitis date to the 1700s, whereas the first accurate study and description were completed by Fitz in 1889. He noted that performing surgery in the early stages of this disease was “extremely hazardous.” Since then, the understanding of pancreatitis has evolved; however, treatment remains largely supportive rather than curative. Advances in care have decreased hospital mortality for all patients with pancreatitis, from 10 to 15% as reported 20 years ago to 4 to 7% more recently. Most patients with pancreatitis have a mild course; however, 10 to 15% of cases will progress to severe disease, with a mortality rate of 20 to 50%. Children are at increased risk for death, with mortality rates of approximately 10%. Severity also is increased in obese patients.

Pancreatitis can be classified as mild or severe, the latter category of the disease being defined by the presence of organ failure or local complications, such as necrosis, pseudo cysts, or abscess. The gravity of the impending illness may not be apparent at the initial presentation, and in all patients, disease progression and outcome are difficult to predict at onset. Death in the first week usually is from pulmonary failure, multiorgan failure, or cardiovascular collapse. Later deaths are more likely to be from infective complications. In approximately 40% of cases, fatal pancreatitis on autopsy was undiagnosed. Therefore, pancreatitis should be suspected in moribund patients with multiorgan failure, particularly elderly persons.

The incidence of acute pancreatitis in the United States ranges from 4.8 per 100,000 to 40 per 100,000, varying with age, gender, and social characteristics of the population studied. The incidence appears to be increasing, although the increase may be related to both improved diagnosis and greater prevalence of risk factors. Gallstones are the most common obstructive cause of pancreatitis and occur more commonly in women than in men, with peak symptomatic incidence between the ages of 50 and 60 years. Some variations of ducal anatomy are associated with increased risk of obstruction. Many gallstones are asymptomatic; however, among people with gallstones, pancreatitis occurs with a frequency of between 8 and 20 per 1000 person-years. Alcoholic pancreatitis is more common in men than in women. In most (but not all) populations, this is the second leading
cause of pancreatitis after obstructive causes. In children, trauma is the most common identifiable cause of acute pancreatitis.\(^4\,13\)

**Principles of Disease**

**Pathophysiology.** Many of the pathobiologic responses such as edema, inflammation, and parenchymal cell death that occur in acute pancreatitis are easy to conceptualize. However, knowledge about the exact molecular mechanisms that go awry within the pancreatic cells and surrounding vasculature that ultimately leads to this cascade of events is still evolving. Intense research to further understanding of pancreatic intracellular digestive enzyme activation, pancreatic inflammatory response, and cell death responses such as necrosis and apoptosis is ongoing, with the aim of identifying new strategies for treatment.\(^4\)

Acute pancreatitis may be divided into three phases that constitute a continuum of pathologic changes. The first phase is the local inflammation that is thought to result from obstruction of the pancreatic or bile ducts, direct toxicity of the pancreatic cells, toxins or infections, and trauma, as well as idiopathic causes. This first phase subsequently causes premature activation of pancreatic enzymes, such as trypsinogen and zymogen, either in the ducts or in the acinar cells.\(^4\,12\,13\) This activation causes the release of enzymes that are intended to digest dietary proteins and fats that instead produce cellular breakdown and pancreatic tissue autodigestion. This is the generalized inflammatory stage. Initially the process is localized, creating focal pancreatic injury and edema. With increasing severity, the inflammation causes necrosis of the pancreas and spreads to the surrounding fat and tissues. There may be necrosis of the pancreatic ducts as well as the vascular structures, leading to hemorrhage.\(^16\,17\) Necrosis involving more than 30% of the pancreas increases both morbidity and mortality.\(^18\)

The enzyme activation, inflammation, and necrosis cause a variety of localized complications. For example, fluid collections develop in 30 to 50% of patients with severe pancreatitis.\(^19\) Over time, a fibrinous or granulation wall may form around this fluid collection, creating a pseudocyst. Thus, pseudocysts are not present in the initial phases of pancreatitis but instead develop over 4 to 6 weeks. Fluid collections, necrotic areas, or pseudocysts may become infected in 1% of cases, usually after several weeks.\(^19\) Additionally, irritation of the surrounding bowel is common, creating bowel wall edema, ileus, and third spacing of fluid. Formation of ascites is common and, together with bowel edema, can lead to significant intravascular fluid loss and hypotension.

The third and final stage occurs with the development of multiorgan damage. Because of the release of inflammatory mediators, the initial localized inflammatory response may cause a systemic immune response syndrome (SIRS), resulting in multiple organ failure. This is a sepsis-like response, and any organ system can be involved, potentially resulting in myocardial depression, acute respiratory distress syndrome (ARDS), disseminated intravascular coagulation (DIC), or renal failure.\(^20\)

**Etiology.** Pancreatitis has a variety of causes, but the vast majority of cases (80%) will be due to either gallstones or alcohol, with gallstones the most common cause in most series (approximately 45% versus 35%).\(^2\,21\) (Box 89-1). The exact pathomechanism of biliary pancreatitis is not clear. Either a stone within the bile duct applies transmural pressure on the pancreatic duct, or a stone in the common channel of the pancreatic duct and common bile duct causes obstruction. Obstruction or pressure on the pancreatic duct causes bile reflex or increased pressure of pancreatic secretions. Either mechanism leads to the activation of pancreatic enzymes, setting off the cascade of pancreatitis. Many cases presumed to be idiopathic probably are due to small stones, sludge, or crystals that are too small to be detected on ultrasound examination but may be seen on endoscopic retrograde cholangiopancreatography (ERCP).\(^22\) Missing this cause will increase the possibility of recurrence.

Alcohol is the cause of approximately 35% of pancreatitis cases. As with the other causes of pancreatitis, the mechanism by which alcohol is toxic to the pancreas is not well understood. Possible mechanisms include toxic effects of the ethanol metabolite acetaldehyde, ethanol-related lipid metabolism, or
spasm of the sphincter of Oddi. Patients with alcoholic pancreatitis have usually had 5 to 10 years of chronic alcohol use before the onset of pancreatitis.5,23

In addition to alcohol, a number of other medications and toxins may cause pancreatitis, including didanosine, pentamidine, oral contraceptives, and selected scorpion venoms. The list of definite and potential drugs causing pancreatitis is extensive (Box 89-2). Another cause of pancreatitis is hypertriglyceridemia, with levels more than 500 mg/dL being implicated, although the level is often above 1000 mg/dL. In pregnancy, both gallstones and increased triglyceride levels can cause pancreatitis.5 When this occurs, both maternal and fetal mortality rates are high (20%).

Both blunt and penetrating abdominal trauma can disrupt the ductal system and the pancreatic cells, setting off the enzyme cascade that will result in acute pancreatitis. Pancreatitis also may result from iatrogenic ductal injury in 1 to 10% of ERCP procedures.24 Likewise, postoperative pancreatitis is well recognized and carries a higher mortality than that associated with other causative disorders.

Although both viral and bacterial disorders may precipitate pancreatitis, the two most common viral causes of pancreatitis are mumps and coxsackievirus B infection. Pancreatitis is more common in patients with human immunodeficiency virus (HIV) infection than in the general population.24 In addition to the common etiologic disorders, this population is at additional risk for opportunistic infections, toxicity from HIV-specific medications, and AIDS-related cancers.25,26 Acute pancreatitis is ultimately classified as idiopathic in approximately 10% of cases.16 Suspected but controversial causes include sphincter of Oddi dysfunction and pancreas divisum, which arises from a failure of the dorsal and ventral ducts to fuse. With this entity, most of the pancreatic juice flows through the minor pancreatic duct and papilla.21

The etiology of pancreatitis in adults and that in children are similar, although incidence rates for specific causative disorders are different. Trauma (including child abuse), infection, and idiopathic causes account for 70% of the cases in children.3 Hereditary pancreatitis is an autosomal dominant trait, with onset frequently noted during childhood. Other causes include infections and congenital anomalies.27 In elderly patients, gallstones are the most common cause of acute pancreatitis, accounting for up to 55% of the cases.28

### Clinical Features

Pancreatitis should be suspected in all patients with epigastric abdominal pain, regardless of age. Once the diagnosis has been made, the underlying cause and presence of complications related to the disease should be sought.
By history, almost all patients have abdominal pain, most commonly in the epigastric region; however, the pain also can be in the right or left upper quadrant. If significant inflammation is present, the pain may be diffuse and the patient may have difficulty localizing the discomfort. Typically, onset of symptoms is relatively rapid, increasing in severity over a few hours. The pain generally is described as constant and severe and may radiate to the mid-back. The degree of pain does not correlate with the severity of disease. Even though gallstones are frequently the cause of pancreatitis, the onset of pain is not usually related to eating. Nausea and vomiting often will accompany the pain. Although the discomfort may be lessened by lying on the side or sitting up, more typically little relief is obtained with position change, moving, eating, vomiting, or bowel movement. Colicky pain or pain that waxes and wanes suggests another diagnosis. Approximately 50% of patients will have a history of similar abdominal pain that may represent a previous episode of biliary colic or mild pancreatitis.

On physical examination, vital signs may be abnormal. Hypotension, tachycardia, and shock indicate severe disease with complications or an alternate diagnosis. Vital signs also may be influenced by pain (tachycardia, tachypnea, hypertension) or alcohol withdrawal (tachycardia, hypotension, fever). A low-grade fever is present in approximately one half of patients with pancreatitis, both at presentation and for the first several days thereafter in the absence of infection. High fever is uncommon during the acute phase of pancreatitis because infection generally is a late complication. Ongoing evaluation should include pulse oximetry because acute hypoxia is an indicator of systemic complications and severe disease.

Patients with pancreatitis generally appear restless and in moderate distress as they search to find a position to relieve their discomfort. They may be jaundiced if an obstructing stone is present. The cardiopulmonary examination may be significant for rales or diminished breath sounds if the patient is hypoventilating from pain or if a pleural effusion (developing more commonly on the left) is present. On inspection, the abdomen may appear normal or may be notably distended. Only rarely will there be evidence of blood within the peritoneum or retroperitoneum resulting from severe hemorrhagic pancreatitis. Presence of blood within these areas is classically manifested as Cullen’s sign (discoloration around the umbilicus) or Grey Turner’s sign (discoloration of the flank). Auscultation of the abdomen may reveal normal, decreased, or absent bowel sounds, depending on whether the patient has a concomitant ileus. Because the pancreas is a retroperitoneal organ, palpation of the abdomen generally reveals epigastric guarding, rebound tenderness being a less common finding. Murphy’s sign may be present if the pancreatitis is secondary to a biliary source. Very rarely the physician may see evidence of subcutaneous fat necrosis: red nodules most prominent on the extremities. Other physical findings, such as the stigmata of alcoholism or xanthomas of hyperlipidemia, may help point to the etiology of the pancreatitis.

### Complications

The patient presenting with acute pancreatitis will often have fever, tachycardia, and leukocytosis; these findings represent three of the four criteria for SIRS. That such a patient might go on to suffer from complications such as fulminant sepsis or other problems related to the intense localized inflammation should not be surprising.

Shock may result from volume loss from multiple sources. Fluid sequestration occurs in both the pancreas and the bowel lumen and wall. Hemorrhage into necrotic pancreatic tissue also may be noted. Additionally, release of vasodilator and cardioactive substances may occur.

Approximately 18 to 30% of patients may have pulmonary complications, which may include degradation of surfactant by pancreatic phospholipases; pleural effusions (more commonly noted on the left and frequently elevated amylase); hypoxia from atelectasis, hypoventilation, and intrapulmonary shunting; and ARDS. ARDS, due to the loss of surfactant as well as capillary leak caused by the inflammatory mediators, is rare but carries a 60% mortality rate. Metabolic complications of pancreatitis include both hyperglycemia and hypocalcemia. Hyperglycemia is caused by decreased insulin and increased glucagon. The mechanisms for hypocalcemia are (1) sequestration or saponification of calcium in areas of fat necrosis; (2) hypoalbuminemia, hypomagnesemia, hyperglucagonemia; and (3) inactivation of parathyroid hormone.

Coagulopathy develops from circulating proteases affecting the coagulation cascade. Acute tubular necrosis can cause acute renal failure and results from the effects of circulating inflammatory mediators or from hypotension and hypoperfusion. Ultimately, multisystem organ failure will occur if the balance of proinflammatory cytokine production overwhelms the anti-inflammatory response, which seeks to restrict the inappropriate movement of proinflammatory agents into the circulation.

Late complications occur after the second week of illness and include involvement of local structures, abscess formation (1 to 4%), gastrointestinal bleeding from stress ulcers, splenic vein thrombosis, rupture of pancreatic pseudocysts, fistula formation, splenic rupture, venous thrombosis, and right hydronephrosis. Pancreatic pseudocysts develop in 1 to 8% of patients after 4 to 6 weeks and are more common with alcoholic pancreatitis (Fig. 89-2). Long-term complications of pancreatitis include recurrent or chronic pancreatitis, diabetes mellitus, and digestive and malabsorption problems.
The diagnosis of acute pancreatitis and the differentiation from other abdominal disorders depend on careful clinical assessment in conjunction with abnormalities on certain laboratory tests and supportive radiographic findings. Three enzymes are derived from pancreatic acinar cells: amylase, lipase, and the proenzyme trypsinogen. Each has been tested as a biochemical marker of acute pancreatitis, but elevation of amylase remains the cornerstone of the diagnosis of pancreatitis, although it is an imperfect assay.

**Amylase Assay.** Amylase is an enzyme that cleaves carbohydrates. It is produced primarily in the salivary glands and pancreas, although it also can be found in small amounts in the fallopian tubes, ovary, testis, muscle, intestines, and other organs. Elevations of amylase may be seen in normal persons as well as in ectopic pregnancy, macroamylasemia (amylase is bound to immunoglobulins or polysaccharides to form large-molecular-weight complexes), parotitis, renal failure (decreased clearance), mesenteric ischemia, bowel obstruction or infarction, perforated duodenal ulcer, acute peritonitis from other causes, and other diseases. Pancreatic amylase can be differentiated from these other sources by electrophoresis, a test that is not readily available in the ED. Because of the other nonspecific sources of amylase, elevations of amylase lack specificity for the diagnosis of pancreatitis. In acute pancreatitis, amylase rises within 6 to 24 hours and peaks in 48 hours, normalizing in 3 to 7 days. Thus, sensitivity of amylase decreases after the first 24 to 48 hours.

In addition to the unclear origin of amylase, several other limitations are recognized for use of amylase assay to diagnose acute pancreatitis. The application of different assays and the lack of an international standard have led to designation of various measured levels as “normal” or “elevated” across institutions. Complicating matters is the lack of universal modality for the diagnosis of pancreatitis; amylase assay, autopsy, computed tomography (CT), and laparoscopy all have been used. Thus, amylase assay is commonly used as an imperfect standard with which to make the diagnosis of pancreatitis because of its low cost and rapid availability. However, it is difficult to determine the precise value of this test to the clinician trying to make the initial diagnosis, particularly in cases with an unclear clinical presentation. As reported by one study, the sensitivity of amylase for the diagnosis of pancreatitis ranges from 79 to 95%, depending on the comparative choice of standard test. As expected, the sensitivity and specificity of amylase vary in accordance with the cutoff value selected to make the diagnosis of pancreatitis. With a cutoff value of total amylase that is at the upper limit of normal, the sensitivity is 91 to 100%, but the specificity is 71 to 98%. Increasing the cutoff value to approximately three times the normal value increases the specificity to nearly 100% but decreases the sensitivity to as low as 61%. The higher cutoff for amylase gives a related drop in sensitivity, which is unacceptable for a serious disease such as acute pancreatitis. In up to 25% of patients with pancreatitis, especially in alcoholics and patients with hypertriglyceridemia (which interferes with the assay), the amylase can be normal. Of importance, mild amylase elevations in patients presenting with acute abdominal pain of unclear etiology, particularly in elderly persons, should raise suspicion for an acute surgical abdomen. Essentially, amylase levels alone, whether normal, mildly elevated, or extremely elevated, do not diagnose pancreatitis unless accompanied by the appropriate clinical picture.

**Lipase Assay.** Lipase is a pancreatic enzyme that hydrolyzes triglycerides and has been used both as an adjunctive test and an alternative test for the diagnosis of pancreatitis. Unfortunately, use of lipase assays is associated with many of the same pitfalls as for amylase assays. In the presence of pancreatic inflammation, lipase levels increase within 4 to 8 hours and peak at 24 hours. The levels stay elevated longer than with amylase, falling over 8 to 14 days, thus giving greater sensitivity in patients with delayed presentation. Lipase, like amylase, is present in other tissues and tends to be elevated in similar clinical situations. Improved assays have rendered lipase more specific than amylase. Yet, there are still nonpancreatic causes of elevations of lipase, such as duodenal ulcers and bowel obstruction, as well as idiopathic elevations. Comparisons between amylase and lipase are limited by the lack of a true “gold standard” modality for the diagnosis of pancreatitis, as well as the choice of cutoff values used for the diagnosis. Despite these limitations, lipase is at least as sensitive as and probably more specific than amylase (specificity of 80 to 99%). At values 5 times the upper limits of normal, lipase is 60% sensitive and 100% specific. The use of twice the upper limit of normal for lipase values has been recommended to decrease the possibility of missing the diagnosis of pancreatitis. Using elevation of either amylase or lipase as evidence of disease will increase the sensitivity but decrease the specificity. Requiring both levels to be elevated does the reverse. Several experts recommend using lipase over amylase when seeking the diagnosis, and the United Kingdom recently released guidelines that recommend the use of lipase over amylase.

The degree of elevation of amylase or lipase is not a marker of disease severity. In a study of patients with pancreatitis, disease severity was equivalent in those with amylase elevation by less than 3 times normal and in those with higher elevations of amylase. In fact, compared with nonalcoholic patients, alcoholics will frequently have lower amylase levels but may have more severe disease. In a patient with prolonged abdominal pain or a history of pancreatitis, an elevated amylase level for longer than a week may suggest pseudocyst or pancreatic abscess. Use of the amylase-to-lipase ratio has not proved helpful in the determination of a specific cause of pancreatitis.
two major forms, with trypsinogen-2 present in high serum concentrations in acute pancreatitis. In a recent study, the sensitivity and specificity for urinary trypsinogen-2 dipstick testing were 93% and 92%, respectively. At present, however, neither this test nor any others have proved useful enough for inclusion in standard practice.16,35,40

### Additional Laboratory Evaluation

In evaluating a patient with abdominal pain, amylase or lipase assays, along with other blood tests, are necessary to narrow the differential diagnosis, detect complications, and determine prognosis. Ranson developed a two-step list of primarily laboratory parameters, performed at hospital admission and after 48 hours, to determine the risk of death from pancreatitis41,42 (Box 89-3). With this in mind, additional testing should consist of a complete blood count (CBC), lactate dehydrogenase (LDH) determination, and a comprehensive metabolic panel (including measurement of liver enzymes, calcium, renal function, and glucose). In patients with liver disease, coagulation studies should be performed to determine the degree of liver dysfunction. Arterial blood gas analysis should be done selectively in patients who are acidic or hypoxic. This information can be used for treatment decisions and to determine prognosis based on Ranson’s criteria. Magnesium should be checked in alcoholic patients and in those patients with electrolyte abnormalities. Both hypocalcemia and hyperglycemia are common in pancreatitis, with the hyperglycemia resulting from glucagon and insulin abnormalities. Calcium is best determined using the ionized calcium level. Serum calcium is falsely low in the presence of low albumin levels, as may be seen in patients with pancreatitis. Elevations of creatinine and blood urea nitrogen (BUN) may indicate the presence of hypovolemia or renal involvement, or both.

Elevation in liver enzymes may result from biliary-induced pancreatitis or from other diseases of the liver or biliary tract. In addition, liver enzyme levels may increase from the presence on the common bile duct that results from the surrounding pancreatic inflammation. Mild elevations of bilirubin are common in all types of pancreatitis, as well as in many other liver disorders. For the patient diagnosed with pancreatitis, higher elevations of aspartate transaminase (AST) and LDH are related to worse prognosis according to Ranson’s criteria.

When liver enzymes are elevated, the pattern of elevation may help determine the underlying cause of the pancreatitis (Table 89-1). Alanine aminotransferase (ALT) is the best single marker for a biliary etiology; levels greater than 3 times baseline support the diagnosis of biliary pancreatitis.46,43 The higher the elevation of ALT, the greater the specificity and predictive value for gallstones. ALT levels more than 150 IU/L have 96% specificity, positive predictive value (PPV) of 95%, and 48% sensitivity for gallstone pancreatitis. Significant rises in AST, alkaline phosphatase, and bilirubin also are more likely to be related to biliary pancreatitis but are not as sensitive as ALT.43

The CBC may be notable for an elevated white blood cell count; the hematocrit may be either high or low. Early in the course, the hematocrit may be elevated because of third space volume loss. A decrease in hematocrit is a poor predictor of prognosis because it indicates intra-abdominal hemorrhage and severe pancreatitis. An electrocardiogram also should be done early to determine whether the patient’s abdominal pain may be cardiac in origin.

### Prognosis

At present, a variety of markers are available to aid in the detection of severe pancreatitis, including specific laboratory values that measure the systemic inflammatory response, scoring systems that tabulate the extent of inflammation or organ failure, and findings on imaging studies. The most commonly used scoring system is Ranson’s criteria (see Box 89-3). In this system, the five criteria evaluated on hospital admission and after 48 hours reflect the development of systemic complications. Ranson recognized that the model did not work well for patients with gallstone pancreatitis, so he revised the criteria to reflect the improved mortality. Although Ranson’s criteria have an 89% negative predictive value, the obvious drawback to use of this system in the ED is that the scoring cannot be completed until 48 hours after diagnosis.44,45 Furthermore, in patients with AIDS, Ranson’s criteria may not be as accurate because of HIV-induced changes in the laboratory values such as those of calcium and LDH.45,26

Severe of disease in patients with acute pancreatitis, the evaluation of pancreatitis. Magnetic resonance imaging

In pancreatitis, abdominal radiographs may show an ileus with a sentinel jejunal loop or spasm of the transverse colon and dilatation of the ascending colon. Pancreatic calcifications of chronic pancreatitis or gallstones may rarely be seen. The portion of the chest seen as part of the abdominal series may show left-sided or bilateral pleural effusions, atelectasis, or ARDS. Up to 80% of radiographs obtained in patients with pancreatitis will demonstrate some abnormality. Unfortunately, many of these findings are nonspecific, and plain radiography has largely been replaced by more advanced imaging.

CT and ultrasound imaging are complementary studies in the evaluation of pancreatitis. Magnetic resonance imaging (MRI) offers imaging similar to that achieved with CT without significant advantages. Ultrasonography images the biliary tract with better accuracy than CT; however, the pancreas itself as well as local complications is less well visualized by this modality. It is recommended that an ultrasound study be performed within the first 24 hours of admission, particularly if a biliary etiology is suspected, to determine whether gallstones or dilation of the common bile duct is present. In one study that compared the results of CT and ultrasonography among patients with pancreatitis, ultrasound findings resulted in a change in treatment in 55% of patients, compared with no changes after CT. CT was 39% sensitive for biliary disease, whereas ultrasonography was 83% sensitive. In another study, ultrasound imaging was 94% sensitive for gallstones but only 19% for common duct stones and 38% for common duct dilatation. Because of these limitations, when gallstone pancreatitis is highly suspected, an endoscopic ultrasound study may be more accurate and can help guide the emergency use of ERCP.

Although ultrasound imaging is more sensitive for investigating biliary causes of pancreatitis, there are several reasons to perform CT in pancreatitis. The first is to rule out other causes of abdominal pain; the second is to evaluate for the presence of peripancreatic complications such as hemorrhage, pseudocyst, abscess, or vascular abnormalities; and the third is to help determine the extent of any pancreatic necrosis. The Atlanta International Symposium recommended CT in patients with (1) an uncertain diagnosis; (2) severe clinical pancreatitis, abdominal distention, tenderness, fever with temperatures higher than 102°F, and leukocytosis; (3) a Ranson score greater than 3 or APACHE score greater than 8; (4) no improvement within 72 hours; and (5) acute deterioration. If the diagnosis is clear and evidence of obstruction is lacking, CT or ultrasound imaging can be delayed until after the patient has been admitted to the hospital. The main indication for obtaining a CT in the ED is to exclude other diagnoses; however, if the patient is significantly ill and can tolerate the procedure, early CT may help determine if complications are already present.

If a CT scan is obtained, a dynamic helical CT study with oral and intravenous contrast is recommended. This study will help differentiate unopacified bowel from a pancreatic abscess or pseudocyst. Recent studies have shown that contrast does not aggravate pancreatitis in humans; however, if the patient cannot tolerate contrast, a noncontrast study will still be helpful. CT also may be used to stage the severity and prognosis of acute pancreatitis. Grades A (no abnormality) and B (focal or diffuse pancreatic enlargement) indicate lower levels of inflammation. Grade C shows mild peripancreatic inflammation and is associated with an increased risk of complication. Grade D (enlarged pancreas with fluid in the anterior pararenal space) and grade E (enlarged pancreas with two or more fluid collections) are associated with significant risk of infection, with mortality rates of up to 15%. The CT severity index is an additional grading system that uses the CT to evaluate how the pancreas looks, as well as evidence of fluid collections or gas adjacent to the pancreas.

Differential Considerations

Pancreatitis must be differentiated from other abdominal processes, cardiopulmonary disorders, and systemic diseases. An important point is that a number of acute surgical conditions may mimic pancreatitis in presentation and

---

**Box 89-4: Atlanta Criteria for Predicting Severe Acute Pancreatitis**

Criteria for severe acute pancreatitis—one or more of the following:

1. Ranson score 3 or higher on admission (or during the first 48 hours)
2. APACHE II score 8 or higher at any time during course
3. Presence of organ failure
   - Shock (systolic blood pressure less than 90 mm Hg)
   - Pulmonary insufficiency (PaO₂ 60 mm Hg or less on room air)
   - Renal failure (serum creatinine >2 mg/dL after fluid resuscitation)
4. Systemic complications
   - DIC (thrombocytopenia and hypofibrinogenemia and fibrin split products)
   - Metabolic complications (serum calcium 7.5 mg/dL or less)
5. Presence of one or more local complications (pancreatic necrosis, pancreatic abscess, pancreatic pseudocyst)

APACHE II, Acute Physiology and Chronic Health Evaluation II; DIC, disseminated intravascular coagulation.

Objective four is reevaluation for complications of pancreatitis. Hypotension should be corrected with large volumes of normal saline (up to 6 L). Invasive hemodynamic monitoring may become necessary. Airway control is appropriate for respiratory failure or continued shock. Hyperglycemia should be treated cautiously because it may self-correct as the pancreatitis resolves. Hypocalcemia may be the result of decreased albumin or hypomagnesemia, so ionized calcium and magnesium levels should be checked before replacement therapy is initiated. If true hypocalcemia is present and the patient is experiencing symptoms, then treatment is appropriate. Calcium gluconate should be used if the calcium must be replenished. The serum potassium should be normalized before calcium replacement, however, because calcium will cause intravascular potassium shifts.

In the case of gallstone pancreatitis, gastroenterology consultation is appropriate to discuss the use of ERCP. Early operative removal of gallstones and the gallbladder has been shown to increase mortality; however, early removal of common bile duct stones by ERCP may reduce morbidity. At present, consensus is lacking regarding the optimal timing of ERCP in the presence of gallstone pancreatitis. Early endoscopic sphincterotomy (in 24 to 48 hours) and stone removal are recommended in the setting of cholangitis, sepsis, and severe obstructive pancreatitis. In mild pancreatitis, early ERCP has not consistently been shown to decrease morbidity. In addition, there is approximately a 5% rate of pancreatitis with ERCP and papillotomy, as well as other complications associated with the procedure (bleeding and perforation). In view of the ongoing controversy, it is appropriate to involve the consultant early in the case so that a well-coordinated plan can be created.

Theoretically, the following medications should moderate the course of pancreatitis: Histamine H 2 receptor blockers decrease the release of secretin by inhibition of gastric acid, glucagon directly suppresses pancreatic exocrine secretion, and octreotide inhibits pancreatic secretion. However, these therapies have not been shown to be clinically effective. Other approaches using inhibitors of inflammatory mediators also have failed to show clinical improvement. For patients with severe pancreatitis, an H 2 blocker, although not helpful for the acute disease, may decrease stress-induced ulcers. Use of antibiotics in those patients with severe pancreatitis with or without evidence of necrosis of pancreatic tissue is controversial. Prophylactic antibiotics have been reported to be effective in reducing subsequent infection. These positive effects have not been seen in all studies, however, and some evidence indicates that use of prophylactic antibiotics in any patient with severe pancreatitis may increase the risk of fungal infection. A recent study with good methodology compared intravenous ciprofloxacin plus metronidazole with placebo and found no difference with respect to the development of infected pancreatic necrosis. At this time, the literature regarding the use of early antibiotics remains unsettled, although there appears to be growing acceptance of withholding antibiotics until clear evidence of infection is present. On the basis of this reality, early discussion with a consultant would be prudent, and in the absence of expert opinion, it remains reasonable to begin broad-spectrum antibiotics in those patients with severe acute pancreatitis.

Surgical intervention or percutaneous drainage may be necessary for cases of infected pancreatic necrosis, infected pseudocyst, or unresolved pseudocyst. Surgery is preferred when percutaneous drainage is not effective or not possible (as with extensive pancreatic necrosis or deteriorating clinical status).

1180

Pancreatitis (cassava fruit is implicated). In idiopathic chronic pancreatitis, increases with the duration and amount of alcohol consumption. Persistent abstinence of alcohol use, although it is more commonly associated with the development of chronic pancreatitis; this form of the disease affects 3 to 15% of chronic alcoholics. It is possible that chronic pancreatitis may develop in persons sensitive to small amounts of alcohol. Three theories exist as to the mechanisms by which alcohol causes chronic pancreatitis have been proposed: (1) direct cellular toxicity, (2) alcohol-induced precipitation of proteinaceous fluid in the ductules, which causes obstruction and calcification, and (3) injury caused by recurrent acute pancreatitis leading to irreversible damage and chronic inflammation. Chronic pancreatitis can continue even after the cessation of alcohol use, although it is more commonly associated with alcoholic relapse.

Other, less common causes of chronic pancreatitis include ducal obstruction, autoimmune pancreatitis, hereditary pancreatitis, cystic fibrosis, trauma, autoimmune, hyperparathyroidism, α1-antitrypsin deficiency, hyperlipidemia, and tropical pancreatitis (cassava fruit is implicated). Idiopathic chronic pancreatitis occurs in approximately 10% of patients. In the 25% of cases of unknown cause, occult alcohol use may be the culprit. In children the most common causes are cystic fibrosis and hereditary pancreatitis.

The pathophysiology of chronic pancreatitis includes chronic calcific pancreatitis, usually seen in alcoholics and characterized by patchy fibrosis, ductal injury, intraductal protein plugs, stones, and chronic inflammatory pancreatitis with diffuse fibrosis and inflammatory changes. As in acute pancreatitis, chronic inflammation can cause local injury resulting in lesions such as pseudoaneurysms, splenic vein thrombosis, pancreatic ascites, or pancreatic fistulas. Pancreatic pseudocyst formation is seen in up to 25% of patients with chronic pancreatitis. Rarely, pseudocysts can erode into vascular structures or can become infected. Narrowing of the bile duct from extrinsic pressure or strictures may lead to elevation of liver enzymes and jaundice. In approximately 5% of patients, duodenal obstruction develops secondary to inflammation around the head of the pancreas. Thus, chronic pancreatitis in an acutely ill patient may be a manifestation of the primary disease or a complication.

The most common endocrine complication is the presence of glucose intolerance in many patients with chronic pancreatitis. Over years, insulin-dependent diabetes develops in 50 to 75% of patients. Patients with chronic pancreatitis also may develop in persons sensitive to small amounts of alcohol. Three theories exist as to the mechanisms by which alcohol causes chronic pancreatitis have been proposed: (1) direct cellular toxicity, (2) alcohol-induced precipitation of proteinaceous fluid in the ductules, which causes obstruction and calcification, and (3) injury caused by recurrent acute pancreatitis leading to irreversible damage and chronic inflammation. Chronic pancreatitis can continue even after the cessation of alcohol use, although it is more commonly associated with alcoholic relapse.

levels of amylase and lipase initially are mildly elevated in chronic pancreatitis, but as the disease progresses, these levels normalize. As in acute pancreatitis, the degree of elevation of amylase and lipase is not predictive. In the patient with the appropriate clinical picture, normal amylase and lipase levels are consistent with a diagnosis of chronic pancreatitis.

Blood work should include a CBC and complete metabolic profile. The white blood cell count usually is normal. There may be elevations of hepatic enzymes (alkaline phosphatase, bilirubin, or transaminases) either from alcoholic hepatitis or from compression on the biliary duct from pancreatic inflammation or as a mass in the head of the pancreas. Elevations in serum glucose also may be seen; hypoglycemia is less common. Decreases in albumin and calcium are common because of the chronic nature of the disease. If the diagnosis is in question, stool may be tested for fecal fat and pancreatic enzymes such as elastase, chymotrysinogen, and trypsinogen.21

Although abdominal radiographs are not necessary, presence of pancreatic calcifications is pathognomonic. Such calcifications are seen in 30 to 50% of patients, usually related to chronic alcohol-induced pancreatitis (Fig. 89-3). Patients with calcifications have had pancreatitis for an average of several years; therefore, these patients should be evaluated for long-term complications such as diabetes and malabsorption.

In patients with the clinical manifestations of chronic pancreatitis, including pain, malabsorption, and diabetes, the diagnosis is made by CT scan, ERCP, or endoscopic ultrasound.22 In the ED setting, patients with known chronic pancreatitis do not need imaging except when the underlying cause of the pain is in question or if the pain is prolonged, significantly increased, or unresponsive to treatment. CT shows dilated intrapancreatic ducts, microcalcifications, pseudocysts, or other complications. CT is 90% sensitive for chronic pancreatitis and is the preferred modality when imaging is indicated. Although ultrasound imaging is useful in diagnosing the cause of acute pancreatitis, it is less useful in chronic pancreatitis, with a sensitivity of 75% and specificity of 80 to 90%. The primary ultrasound findings are pancreatic calcifications and ductal abnormalities.

Although endoscopic retrograde pancreatography (ERP) is not an ED procedure, it can be helpful in diagnosing pancreatic duct abnormalities and measuring pancreatic function. Some gastroenterologists consider the ductal abnormalities seen on ERP and endoscopic ultrasound to be pathognomonic for chronic pancreatitis. In the future, MRCP may assume a greater role in the evaluation of chronic pancreatitis.22

Differential Considerations

The diagnosis of chronic pancreatitis usually is straightforward in the alcoholic patient with hyperamylasemia who has chronic abdominal pain and a history of similar, previous flares of pancreatitis. The diagnosis may be more difficult when amylase and lipase levels are normal. However, the clinician should not be lulled into complacency and forget that other abdominal processes, unrelated to either the pancreas or the complications of pancreatitis, are legitimate considerations in the differential diagnosis (see Box 89-5). In addition, other chronic abdominal disease such as peptic ulcers, irritable bowel, gallstones, and endometriosis may manifest with recurrent abdominal pain. Finally, narcotic-dependent patients in withdrawal may experience vomiting and abdominal pain that may be difficult to differentiate from chronic pancreatitis.

Management

The initial management of chronic pancreatitis is supportive. Depending on the patient’s clinical status and electrolyte values, replenishment of fluids and electrolytes may be necessary. An “alcohol cocktail” with thiamine, multivitamins, and folic acid is often indicated because patients frequently are malnourished. Antiemetics should be used to manage recurrent emesis.

Management of pain is one of the most important and most difficult aspects of treatment. Laboratory values may be normal despite significant pain, and patients with chronic pain syndromes may not exhibit signs of autonomic hyperactivity when experiencing exacerbations of their underlying disease. This lack of correlation may lead to a concern that the expressed need for pain medication constitutes drug-seeking behavior. Physicians should err on the side of treatment in most patients, except those with documented abuse. Nonsteroidal analgesics and acetaminophen are the preferred drugs for control of pain but often are not adequate. Either morphine or meperidine may be used and should be titrated to effect. Tramadol (Ultram) also has been used effectively.23 The use of narcotics over extended periods may be necessary. Non-narcotic modulators of pain, such as selective serotonin reuptake inhibitors or gabapentin, may be helpful for chronic pain. In the ideal medical system, the primary care physician or a pain management specialist monitors the narcotic prescription, because narcotic dependence may become an issue.

The removal of inciting factors, especially alcohol, is important. Smoking also plays a role in the development of chronic pancreatitis that is independent of alcohol.27 Patients with significant pain should have nothing by mouth, although as in acute pancreatitis, a nasogastric tube is not indicated. The use of oral pancreatic replacement enzymes increases the amount of trypsin in the duodenum and may decrease stimulation of the pancreas, with subsequent decrease in pain. Studies of the effectiveness of pancreatic enzyme replacement on pain have yielded contradictory results.27 These enzymes should be used in patients with malabsorption or steatorrhea. In theory, proton pump inhibitors or H₂ receptor blockers also may reduce pancreatic stimulation; however, these agents have not been shown to decrease pain or hasten recovery. Octreotide lowers cholecystokinin levels and may inhibit pancreatic secretion.27

Figure 89-3. Pancreatic calcifications (arrowheads) throughout the pancreas as seen in chronic pancreatitis. (Incidental finding of feeding tube in main bronchus.) (Image courtesy of Ronald Arildsen.)
Beyond ED treatment, helpful adjuncts may include endoscopic dilation, ductal stone removal, extracorporeal shock wave lithotripsy, or stenting of the pancreatic ducts. Common bile duct stenting also may be necessary, because obstruction occurs in approximately 5 to 10% of cases.71 Surgery such as pancreatic head resection, lateral pancreaticojunostomy, or Whipple pancreatic duodenectomy is sometimes an option when conservative treatment has failed. One recent study showed improved pain and physical health summary scores in patients randomized to undergo surgery rather than endoscopy.74 Pancreatic pseudocysts in chronic pancreatitis are less likely to resolve spontaneously and should be drained either endoscopically under ultrasound guidance or in an open procedure. Celiac plexus blocks also have been used with minimal success for pain control.

Disposition

In general, patients with chronic pancreatitis are managed as outpatients and present to the ED with exacerbations or complications. Because acute pancreatitis can occur in patients with chronic pancreatitis, the same prognostic indicators for severity of acute pancreatitis should be considered. Patients with severe disease should be admitted to the ICU. Patients with dehydration, abdominal pain unresponsive to medication, or questionable diagnosis should be hospitalized for evaluation and treatment. After a careful ED evaluation, in the absence of dehydration, unstable vital signs, or uncontrolled pain, the patient may be managed on an outpatient basis with close follow-up. After hospital discharge, it is important to stress lifestyle modifications of abstinence from alcohol and tobacco, as well as intake of frequent, small low-fat meals.

PANCREATIC CANCER

Perspective

Pancreatic cancer is a particularly lethal cancer, with a 5-year survival rate of 4% despite aggressive surgery and advances in chemotherapy. It is the fourth most common cause of cancer-related death in the United States. The disease is diagnosed in approximately 11 people per 100,000 per year, and the incidence has increased three-fold over the past 40 years. Because early symptoms are few, a minority of patients (less than 20%) are diagnosed at an early stage.26,75,76

Principles of Disease

Little is known about the etiology of pancreatic cancer. The most consistently reported risk factors are smoking, advanced age, and positive family history. Chronic alcoholism, chronic pancreatitis, and diabetes have been shown to be risk factors in some studies.76-78

Ductal adenocarcinomas account for 95% of malignant pancreatic tumors. The pancreatic head is the location of origin in 70% of cases. The tumor extends locally into adjacent structures and can metastasize by hematogenous or lymphatic spread to liver, peritoneum, lungs, bones, and brain. Neuroendocrine tumors, such as gastrinomas, vasoactive intestinal peptide (VIP)-omas, and glucagonomas make up the remaining cases.79 These types of tumors carry a better prognosis.

Clinical Features

The presentation of pancreatic adenocarcinoma is variable because progression of the disease is indolent. The tumor usually has been present for several months before the cancer is diagnosed; therefore, patients may present with pain of long duration or with one of the many complications of the disease.80 One of the most common presentations is weight loss, which usually is the result of anorexia rather than malabsorption. The patient may complain of dull, constant abdominal pain in the epigastrium that may radiate to the back. Alternatively, the patient may present with painless jaundice from common bile duct obstruction, and progressive jaundice develops in approximately 75% of patients. An enlarged, palpable, but painless gallbladder in the presence of jaundice is most commonly associated with pancreatic cancer (termed Courvoisier’s sign). Glucose intolerance also may develop. As the tumor enlarges, patients may exhibit evidence of bowel obstruction. Pancreatic cancer (as well as other cancers) may render patients hypercoagulable, resulting in thromboembolic presentations. Varices and gastrointestinal bleeding may be caused by compression of the portal system.

Neuroendocrine tumors of the pancreas are rare and manifest with symptoms that reflect the hormones they produce. For example, with insulinomas, the presenting manifestation may be hypoglycemia. Gastrinomas are related to Zollinger-Ellison syndrome and recurrent peptic ulcers. VIPomas (also known as Verner-Morrison syndrome) manifest with extreme watery diarrhea, hypokalemia, and achlorhydria. Glucagonomas manifest with glucose intolerance and necrolytic migratory erythema. Some tumors produce multiple hormones.79 Other, nonfunctional tumors also may be noted incidentally on CT scans as small pancreatic masses. Diagnosis is made by measurement of abnormal levels of hormones and recognition of the appropriate clinical syndrome. Fifty percent of pancreatic neuroendocrine tumors are malignant.81

Diagnostic Strategies

The diagnosis of pancreatic cancer may be made by ultrasonography, although CT scan provides better imaging of the cancer. MRI also may provide information. Percutaneous ultrasound-guided biopsy, endoscopic ultrasound examination and biopsy, or CT-guided biopsy can be used to obtain tissue diagnosis.77 Histologic samples are needed to differentiate ductal adenocarcinoma from islet cell tumors, other metastatic cancers, and lymphoma. Serologic markers have not proved satisfactory for diagnosis or follow-up evaluation, although several oncogenes and tumor markers are under study (CA19-9 and CEA).

Management

Complete resection of the carcinoma is the only effective treatment. Unfortunately, few tumors (less than 20%) are diagnosed at a stage at which this may be possible.77 In patients with unresectable tumors, the median survival period is approximately 6 months. Palliative surgery may be performed to relieve obstruction. Biliary drainage by percutaneously placed or ERCP-placed stents also may help to relieve jaundice. Chemotherapy and radiation therapy may decrease tumor size to ease pain and prolong survival in some patients.77,82 Treatment of neuroendocrine tumors is aimed at limiting tumor growth by both excision and reversal of hormone excess.82

Patients may present to the ED with complications of the cancer such as bowel obstruction, jaundice, or problems with pain control. In view of the grim prognosis for this disease and the significant associated pain, narcotics should not be withheld, and end-of-life issues should be addressed by the oncologist.
Most cases of acute pancreatitis are caused by gallstones (45%) and alcoholism (35%). Other causes include medications, toxins, and trauma.

The clinical spectrum of acute pancreatitis ranges from mild (epigastric discomfort often associated with vomiting) to life-threatening (severe abdominal pain in the presence of an acute abdomen and hemodynamic instability due to systemic complications). The mortality rate for severe pancreatitis approaches 30%.

There is no perfect test for diagnosing acute pancreatitis. The most useful tests include serum amylase and lipase assays. Unfortunately, both tests can yield normal results in up to 25% of cases, and mild elevations are not specific for acute pancreatitis and can be seen in many other acute surgical disorders causing abdominal pain. Both tests are highly specific for pancreatitis when serum levels are elevated 5 times above the upper limits of normal.

Emergent abdominal CT should be performed in patients with clinically suspected pancreatitis who appear acutely ill (to exclude peripancreatic complications such as hemorrhage, pseudocyst, or abscess) and in patients with an uncertain diagnosis (to exclude other surgical causes of acute abdominal pain).

Because the course of acute pancreatitis is unpredictable, patients should be hospitalized for pain control, hydration, observation, and the management of complications. Patients with severe pancreatitis (i.e., those who have more than two of Ranson’s criteria, an APACHE score over 7, or evidence of systemic complications) should be cared for in an ICU.

SMALL BOWEL OBSTRUCTION

Perspective

The signs and symptoms of intestinal obstruction have been recognized for centuries. This clinical entity has historically been treated with a variety of interventions, including enemas and inflation of the rectum, metallic mercury ingestion, therapeutic bleeding, and percutaneous intestinal puncture. By the late 19th century, proximal intestinal decompression was reliably used to provide temporary symptomatic relief of intestinal obstruction. Advances in the 20th century and beyond, including the development of antibiotics and improved surgical techniques, have significantly improved the prognosis for patients with small bowel obstruction (SBO).

Obstruction of the small bowel accounts for 15% of hospital admissions for acute abdominal complaints. Approximately 300,000 operations are performed in the United States each year for relief of intestinal obstruction. Aggressive treatment has resulted in a current mortality rate of less than 5%, a substantial improvement over the expected 60% mortality rate for this disease in 1900. When strangulation complicates SBO, however, the mortality rate increases to as much as 30%. Death from SBO occurs most often in the elderly or in patients with significant underlying illness.

The term mechanical obstruction implies a physical barrier to the flow of intestinal contents. Within this definition, simple obstruction refers to the situation in which the intestinal lumen is partially or completely occluded at one or more points, thus producing proximal intestinal distention, but without compromise of the intestinal vascular supply. A closed-loop obstruction implies that a segment of bowel is obstructed at two sequential sites, usually by twisting about a constricting adhesive band or hernia opening. This mechanism of obstruction is associated with a high risk for compromise of intestinal blood flow with resulting intestinal ischemia, a condition referred to as strangulation obstruction. Not all closed-loop obstructions are associated with intestinal ischemia, and other types of obstruction may eventually involve vascular compromise.

In contrast with mechanical obstruction, neurogenic or functional obstruction occurs when intestinal contents fail to pass through the bowel lumen because of disturbances in gut motility rather than actual blockage. This entity also is commonly referred to as adynamic ileus. When intestinal peristalsis fails, dilatation of the involved intestinal tract develops. Adynamic ileus most commonly is seen after abdominal surgery but can be caused by other common medical conditions (Box 90-1).

Focal decrease in peristaltic activity may occur because of a localized inflammatory process (e.g., pancreatitis, cholecystitis, appendicitis) and result in gas and fluid accumulation in an isolated segment of bowel. This segmental ileus is called a sentinel loop.

Pseudo-obstruction refers to a poorly understood disorder of intestinal motility associated with a number of medical conditions, including amyloidosis, collagen vascular disease, diabetes, hypothyroidism, and several metabolic disorders—hypokalemia, hypocalcemia, and uremia. The signs and symptoms of intestinal obstruction are present, but evidence of an underlying lesion or cause is absent on diagnostic evaluation. Correction of any underlying disease process and supportive care are recommended, but the results of treatment often are disappointing.

Principles of Disease

A relationship between the progressive physiologic changes that occur in patients with SBO and the corresponding clinical manifestations is well documented. Mechanical SBO initially causes mild proximal intestinal distention that results from the accumulation of normal gastrointestinal secretions and swallowed air above the obstructing lesion. This distention stimulates peristalsis above and below the obstruction, which accounts for the frequent loose bowel movements that may accompany partial and even complete SBO in the early stages. Early bowel distention stimulates epithelial cell secretory activity, resulting in the addition of more fluid, increasing bowel dilatation, and the creation of a self-perpetuating process. This situation is worsened by the inability of the distended bowel to absorb fluid and electrolytes at a normal rate. Further increases in intraluminal pressure result in capillary and lymphatic obstruction with subsequent edema of the bowel wall. Perforation occurs if this process continues uninterrupted. In addition, vomiting and intraperitoneal fluid sequestration further compound volume losses, leading to extracellular fluid depletion, hypovolemia, and, eventually, shock.

The rise in intraluminal pressure is much more abrupt with a closed-loop obstruction because the intestinal contents also are prevented from retrograde flow. Strangulation occurs, with subsequent development of venous congestion, small vessel rupture, intramural and mesenteric hemorrhage, and arterial insufficiency. It also is not uncommon for the loop of distended bowel to twist on itself further, resulting in large artery
occlusion. Either sequence of events then progresses rapidly from intestinal ischemia to infarction.

Necrosis of the bowel and leakage of contaminated contents cause bacterial peritonitis and sepsis. Although the proximal small bowel normally contains few bacteria, this changes quickly during times of intestinal stasis. Simple intestinal obstruction has been shown to be associated with increased bacterial translocation to mesenteric lymph nodes. In one series, 59% of the patients undergoing laparotomy for simple SBO had bacteria (most commonly *Escherichia coli*) cultured from mesenteric lymph nodes, compared with only 4% of patients operated on for other reasons.\(^1\)\(^,\)\(^2\)

The most common causes of SBO are listed in Box 90-2. In developed countries, postoperative adhesions are now responsible for more than 50% of all cases. It is estimated that as many as 15% of abdominal surgeries eventually result in SBO from adhesions. A particularly high incidence of SBO is found after gynecologic or intestinal surgery, as well as in patients who have previously undergone surgery in the presence of peritonitis or significant abdominal trauma.\(^3\)\(^,\)\(^4\) Other important causes of SBO include hernias and neoplasms, each with an incidence of approximately 15%.\(^3\)\(^,\)\(^4\) The incidence of obstruction related to hernias has been steadily decreasing in developed countries because of elective treatment of external hernias.\(^5\) Although hernias account for a relatively small proportion of bowel obstructions, they are associated with a high rate of strangulation (28% with hernias versus 8% with adhesive obstruction). Anatomically, strangulation occurs because many obstructions caused by hernias are of the closed-loop type. When neoplasm is associated with SBO, the cause most often is colon cancer, followed by pancreatic, gastric, and gynecologic malignancies.

Several less common causes of SBO are pertinent to the practice of emergency medicine. *Gallstone ileus* is rare in the general population but accounts for 25% of nonstrangulated SBOs in patients older than 65 years.\(^6\)\(^,\)\(^7\) In this entity, a gallstone erodes through an inflamed gallbladder wall into a loop of adjacent small bowel. The stone then passes through the bowel lumen until it meets some narrowing, typically at the distal ileum, where it produces mechanical obstruction. This problem occurs predominantly in elderly patients, so the associated 15 to 18% mortality rate is not surprising. Another unique cause of SBO is an *obturator hernia*. This hernia typically occurs in elderly emaciated women with significant concomitant medical illness but no previous abdominal surgery. It is believed that women with a wider pelvis and more oblique obturator canal are predisposed to the development of obturator hernia in the presence of decreased preperitoneal fat related to emaciation and chronic increased intra-abdominal pressure related to associated medical disease. This hernia is difficult to detect and often is diagnosed only when it arises as SBO. Both of these uncommon causes of SBO occur in the elderly, a group that is becoming an increasing percentage of the emergency department population.

Another uncommon but noteworthy cause of SBO is *small bowel volvulus*.\(^8\) This condition results from abnormal twisting of a loop of bowel around the axis of its own mesentery. Although volvulus of the colon (sigmoid and cecum) is common, volvulus of the small bowel is rare. Primary small bowel volvulus occurs in an otherwise normal abdominal cavity and is seen most often in adult patients in Africa, the Middle East, and the Indian subcontinent. It is rarely seen in Europe and North America. Secondary causes of small bowel volvulus include malformation and malrotation of the intestine and tethering of the loop of bowel at its apex as a result of postoperative adhesions. Early surgical intervention is important because this classic form of closed-loop obstruction is associated with a high incidence of strangulation.

*Intussusception* occurs in all age groups but is primarily a disease of infancy and early childhood, constituting the most common cause of SBO in early childhood. Only 5% of all intussusceptions occur in adults, and intussusception accounts for only 5% of cases of SBO in adults.\(^9\)\(^,\)\(^10\) An intussusception occurs when a segment of bowel telescopes into an adjacent segment, resulting in obstruction and ischemic injury to the intussuscepting segment. In contrast with the idiopathic nature of most childhood intussusceptions, a mechanical cause is present in more than 90% of adult cases. Tumors, either benign or malignant, act as the lead point of intussusception in more than 65% of adult cases. Several reports have described adult intussusception associated with acquired immunodeficiency syndrome (AIDS). In this setting, the lesions generally are in the ileum, and intussusception has been associated with lymphoma or unusual inflammatory processes, including atypical mycobacterial infection.

Clinical manifestations of intussusception in the adult patient are nonspecific and may occasionally be chronic or recurrent in nature. Abdominal pain is a prominent complaint, often associated with symptoms and signs suggestive of obstruction (nausea, vomiting, and abdominal distention). Radiographic features of intussusception also are nonspecific. Plain films may reveal evidence of partial or complete bowel obstruction. It has been recommended that ultrasonography may be useful in the diagnosis of adult and pediatric cases. The mainstay of diagnosis, however, remains contrast studies, typically abdominal computed tomography (CT) with an oral contrast agent. Although reduction of the intussusception may occur during contrast studies, surgery is recommended for adult patients because of the high incidence of pathologic lesions as a cause of intussusception.\(^10\)
Finally, a fascinating and lengthy list of unusual causes of SBO has been reviewed and includes pharmacobezoars, *Ascaris lumbricoides* infection, and endometriosis. These reportable causes of SBO account for less than 6% of all cases.11

### Clinical Features

**History.** Patients with SBO typically complain of regularly recurrent bouts of poorly localized abdominal pain lasting from seconds to minutes. The painful spasms occur every few minutes with proximal intestinal obstruction and less frequently with more distal obstruction. The pain is described as crampy in nature, and each episode has a characteristic crescendo-decrescendo pattern. A change in the description of the pain from intermittent and colicky to constant and severe may signal the development of complications, such as intestinal ischemia or perforation.

In general, the more proximal the obstruction, the greater the patient’s discomfort and the shorter the delay between onset of symptoms and presentation. Several hours of severe colicky pain in association with bilious vomiting and mild abdominal distention are typical of proximal intestinal obstruction, whereas a day or two of progressively worsening pain and more prominent abdominal distention is typical of distal intestinal obstruction. When vomiting does occur with distal intestinal obstruction, it often is feculent from bacterial proliferation. With complete intestinal obstruction, obstipation eventually develops, whereas with early or partial obstruction, the patient may continue to pass stool or flatu.

**Physical Examination.** The physical examination should begin with a brief but thorough assessment of the patient’s degree of distress, vital signs, and general condition. These important parameters determine the urgency of the evaluation and management of the patient.

Examination of the abdomen should include inspection for distention and a careful search for surgical scars and external hernias. Auscultation may reveal hyperactive bowel sounds—in particular, rushes or high-pitched “tinkles” produced by forceful peristaltic efforts. Late in the course of bowel obstruction, bowel sounds may become hypoactive or may be absent. Percussion may elicit tympany with distal obstruction and ileus. Palpation may reveal a tender mass, especially with a late in the course of bowel obstruction. An electrolyte panel and renal function testing are appropriate if significant volume loss is evident.

Conventional and special radiographic examinations of the abdomen are the most useful diagnostic adjuncts for the evaluation of patients with suspected SBO. These studies may confirm or exclude the presence of bowel obstruction; identify the site, severity, and cause of the obstruction; and help distinguish simple obstruction from strangulation.17-20 Characterization of the obstruction in this manner will determine the need for urgent surgical intervention versus a period of conservative, nonoperative management.

An adequate plain radiographic examination of the abdomen requires at least two films, one with the patient supine and the other with the patient in the upright or decubitus position. An upright chest film may be added to exclude the presence of free subdiaphragmatic gas, an uncommon finding in bowel obstruction. Plain radiographs demonstrate the presence of SBO in 50 to 60% of cases and delineate features suggestive of obstruction in another 20 to 30%.17 The cause of obstruction is rarely demonstrated on conventional abdominal radiographs. The ability to predict the site of obstruction correctly often is limited by fluid-filled loops or abnormal positioning of small bowel. Despite these potential limitations, plain radiography is still the appropriate starting point for the diagnostic evaluation of a patient with suspected SBO.

Typical plain radiographic findings with SBO are distended loops of small bowel proximal to the site of obstruction followed by normal or collapsed bowel distal to the obstruction. The supine view may show dilated loops of bowel that are sharply angulated or arranged in a series of parallel segments reminiscent of a stepladder. Upright or decubitus films may demonstrate multiple intraluminal air-fluid levels (Fig. 90-1A and B). In general, the greater the number of dilated loops of bowel, the more distal the site of obstruction. Colonic gas usually is negligible in amount unless the films are obtained early in the course of the obstruction or in the presence of a partial SBO.

When the obstructed intestine contains more fluid than gas, the classic findings just described may be absent. In this setting, small pockets of gas may become trapped between the valvulae conniventes of the small bowel and may appear as an
oblique series of round radiolucencies on the upright film—the so-called string of pearls or string of beads sign, which is very suggestive of SBO.

In patients with adynamic ileus, plain film findings may be similar to those in patients with intestinal obstruction. With the former entity, however, the radiologic findings tend to involve the entire gastrointestinal tract, including the colon, and air-fluid levels are not as prominent as with mechanical obstruction. The air-filled loops of bowel also are not dilated in gastroenteritis or other causes of adynamic ileus.

Since the first reports describing the role of CT in bowel obstruction in the early 1990s, this modality has been increasingly used. It is considered complementary to standard radiography in the evaluation of SBO. CT has been shown to be an excellent modality for demonstrating intussusception, volvulus, and extraluminal lesions such as abscesses and tumors. This modality is especially helpful and should be used as an early imaging technique in the setting of known abdominal malignancy or inflammatory bowel disease or when an abdominal mass is discovered on examination. CT scans have high sensitivity, specificity, and accuracy in the diagnosis of SBO. In high-grade obstructions, in particular, these numbers are greater than 90%. CT can demonstrate both closed-loop obstruction and features suggestive of strangulation. In the vast majority of cases, CT is not required to make the diagnosis of bowel obstruction. Its main use is in better defining the site of obstruction and possible cause.

Abdominal CT examination has increasingly been advocated for early diagnosis of complete obstruction and ischemia in SBO, both of which dictate early surgical intervention. One recent study demonstrates the high sensitivity for CT for ischemia and further suggests that CT findings consistent with partial SBO predict a clinical condition that will resolve without surgery in more than 90% of cases.

Another radiologic test for small bowel obstruction that may influence clinical outcome is the use of water-soluble contrast. Several studies have shown that water-soluble contrast radiography successfully predicts nonoperative resolution of adhesive SBO. Although some early studies suggested that water-soluble contrast actually hastened resolution of the obstruction, a recent meta-analysis does not support a therapeutic benefit for this technique.

**Differential Considerations**

The diagnosis of SBO should be considered in a patient with abdominal pain and vomiting, especially if the history includes previous abdominal surgery. It often is difficult to distinguish among mechanical obstruction, adynamic ileus, and pseudoobstruction on clinical grounds alone.

Other clinical diagnoses that should be considered range from benign to life-threatening in nature and include pregnancy, gastroenteritis, cholelithiasis and cholecystitis, pancreatitis, peptic ulcer disease, appendicitis, ischemic bowel syndromes, and myocardial infarction. Each of these clinical entities has typical signs, symptoms, and diagnostic findings that help to differentiate it from SBO, but doing so may be challenging when patients present during the early stages of their particular disorder.

**Management and Disposition**

The initial management of SBO has remained largely unchanged for several decades and consists of aggressive fluid resuscitation, bowel decompression, and timely surgical consultation.

All patients with SBO should be admitted to the hospital. Intravenous hydration should be initiated with an isotonic crystalloid solution administered through a large-bore catheter. Enteral decompression by nasogastric suction should take place early in the clinical course to remove accumulated gas and fluid proximal to the obstruction. No convincing argument has been made for the use of a long intestinal tube (e.g., Cantor, Miller-Abbott) over a nasogastric tube. Placement of a nasogastric tube is a noxious procedure for the patient. Application of topical anesthetic to the nasopharynx and posterior pharynx may improve tolerability of the procedure.

There is no convincing research to recommend routine use of antibiotics in the conservatively managed patient. However, the demonstration of bacterial proliferation during intestinal
stasis and obstruction suggests that broad-spectrum antibiotics are appropriate when surgery is planned and when the clinical picture suggests vascular compromise or intestinal perforation. Antibiotic use should provide coverage for gram-negative and anaerobic organisms that colonize the intestinal contents (e.g., second-generation cephalosporins).

“Never let the sun set or rise on a bowel obstruction” is an oft-quoted surgical adage that has stood the test of time because of the preoperative difficulty in distinguishing strangulation from simple bowel obstruction. Proponents of early surgical intervention cite the similar clinical and radiographic presentations of simple and strangulated obstructions and argue that any delay in surgical therapy may increase morbidity. Although there is no debate about the need for surgery in patients with signs of peritoneal irritation or fever, most surgeons advocate a trial of conservative therapy in the absence of findings suggestive of strangulation. Up to 75% of patients with partial SBO and 35 to 50% of those with complete obstruction experience resolution of symptoms when treated with intravenous fluid and bowel decompression alone. Patients with early postoperative bowel obstruction, adhesive obstruction, and obstruction secondary to Crohn’s disease are more likely to respond to nonoperative management. Surgical intervention should be planned if substantial relief is not obtained within a short time after nasogastric tube placement or if symptoms persist after 48 hours of conservative treatment. A practical point is that obstruction occurring in a patient without a previous history of laparotomy is not likely to be caused by peritoneal adhesions. Such de novo obstruction and the underlying cause usually are not resolved without surgery.

Neither advanced age nor known abdominal malignancy is a contraindication to operative intervention. Patients with abdominal cancer who do not have widespread intra-abdominal metastases should be managed as for any other patients with SBO. They should receive a trial of bowel decompression followed by surgery if resolution of the symptoms is not evident. From 20 to 40% of patients with abdominal neoplasms and SBO have a benign cause of the obstruction. In addition, the incidence of strangulation with obstruction related to malignancy is low. Therefore, a trial of tube decompression is a safe and often successful option.

A therapeutic approach that is gaining support for the management of SBO is laparoscopy. Bowl obstruction traditionally has been a relative contraindication to laparoscopy because of the potential for bowel distention and the risk of enteric injury. However, as experience with this surgical approach has increased, surgeons have begun to demonstrate that this is a safe and effective method of diagnosing and treating acute bowel obstruction in selected patients, particularly in those with obstruction caused by adhesions.

---

**KEY CONCEPTS**

- More than 50% of SBO cases are caused by postoperative adhesions. Two other leading causes are various hernias (15%) and neoplasms (15%).
- The diagnosis of SBO usually is made on the basis of plain radiographic findings, with the upright abdominal radiograph revealing air-fluid levels and dilated loops of small bowel in a majority of cases.
- Initial management of SBO should include volume assessment and resuscitation, plain radiography, bowel decompression, and surgical consultation. A significant percentage of SBO cases caused by adhesions may be managed without surgery.

---

**ACUTE MESENTERIC ISCHEMIA**

**Perspective**

Acute mesenteric ischemia primarily affects patients older than 50 years, especially those with significant cardiovascular or systemic disease. The acute form of this disease results in the rapid development of intestinal injury and is much more common than the chronic form of mesenteric ischemia. Chronic mesenteric ischemia results when splanchic blood flow is inadequate to support fully the functional demands of the intestines yet not so compromised as to threaten bowel viability. The incidence of acute mesenteric ischemia is difficult to determine but has been reported as 0.1% of hospital admissions, and increasing occurrence in today’s aging population has been noted in several studies. Acute vascular compromise of the intestine remains an important and life-threatening cause of acute abdominal pain in patients presenting to the emergency department.

Acute mesenteric ischemia was described in the 18th and 19th centuries in sporadic reports; however, an understanding of the underlying pathophysiology awaited the classical experimental work of Litten in 1875, when he described the results of ligation of mesenteric vessels in animals. In 1895, Elliot described the first patient to recover after resection of an infarcted intestine that probably was the result of mesenteric venous thrombosis. He created two stomas and reanastomosed the bowel segments 2 weeks later. Thus, the diagnosis of gangrenous bowel by laparotomy and its treatment by resection with anastomosis, a sequence of events that is still common today, were first performed more than 100 years ago.

The concept of mesenteric revascularization as the treatment for acute mesenteric ischemia was introduced in the 1950s. Even with the advent of this significant surgical advance, however, morbidity and mortality rates remained high. Today, most physicians use an aggressive approach to the patient with suspected acute mesenteric ischemia, as first proposed in the 1970s. The single most important step in this approach is early diagnosis.

The etiology of acute mesenteric ischemia actually has four distinct categories, each associated with a group of risk factors, signs and symptoms on presentation, and varying nuances in the evaluation and management of the patient. The most common cause of acute mesenteric ischemia is arterial embolus, which accounts for 40 to 50% of cases. Arterial thrombosis accounts for 25% of acute presentations, nonocclusive mesenteric ischemia for 20%, and the remaining 5 to 10% of cases are caused by mesenteric venous thrombosis. The importance of early diagnosis and aggressive intervention in patients with suspected acute mesenteric ischemia is underscored by mortality rates that climb to 70% once intestinal infarction has occurred. The mortality associated with this lethal disease has changed little in the last several decades and probably will not decrease until a reliable screening test for the disease is found.

**Principles of Disease**

The severity of intestinal injury is inversely proportional to mesenteric blood flow and is a function of the state of the systemic circulation, the number and caliber of involved vessels, the status of the collateral circulation in the region, and the duration of the ischemia. The extent of the damage ranges from reversible impairments in mucosal function to transmural infarction and necrosis of part or all of the bowel served by the compromised vasculature.

Blood supply to the abdominal organs derives from three major vessels: the celiac artery trunk, the superior mesenteric...
Abdominal organs receive their blood supply on the basis of embryologic development. The esophagus, stomach, proximal duodenum, liver, gallbladder, pancreas, and spleen are supplied by the celiac trunk. The SMA supplies the distal duodenum, jejunum, ileum, and colon to the splenic flexure. The descending and sigmoid colon and rectum are supplied by the IMA. There is an abundant system of collateral vessels with significant territorial overlap of blood flow that can be clinically significant.

Approximately 25% of the cardiac output is delivered to the small and large intestines, with two thirds going to the SMA distribution and one third to the IMA. Eighty percent of this flow is destined for perfusion of the mucosa because of its high metabolic requirement. Accordingly, the visceral mucosa is very sensitive to decreased perfusion. With the onset of hypoperfusion, a redistribution of intramural blood flow favoring the superficial layers of the mucosa takes place. Below a critical level of blood flow, however, the intestinal villi become ischemic, and significant alterations in mucosal function occur.

The countercurrent exchange mechanism in the small intestinal villi initiates and perpetuates ischemic damage to the tissue. As epithelial cells become necrotic, endothelial factors are released that lead to the attraction and activation of neutrophils and macrophages into the ischemic tissue. These cells release protease enzymes, tissue necrosis factor, platelet activating factor, arachidonic acid by-products, and toxic oxygen radicals that cause further endothelial damage, increased vascular permeability, vasoconstriction, inflammation, and further necrosis. This initial ischemic insult is compounded if and when perfusion is reestablished, because restoration of blood flow permits further recruitment of inflammatory cells to the area. Ischemic disruption of the normally impenetrable mucosal barrier allows the release of bacteria, toxins, and vasoactive mediators into the systemic circulation. Cardiac depression, multisystem organ failure, septic shock, and death may occur even before the development of intestinal ischemia. Necrotic changes can be seen as early as 10 to 12 hours after the onset of symptoms but may develop in a more delayed fashion.

**Mesenteric Arterial Embolism**

The median age of patients presenting with mesenteric arterial emboli is 70 years. Approximately two thirds of these patients are women. The vast majority of arterial emboli resulting in acute mesenteric ischemia involve the SMA. The source of SMA emboli usually is the heart, with fragmentation of either left atrial or ventricular thrombi during or after a dysrhythmia or valvular lesions. Emboli consisting of tumor and cholesterol also have been described. Emboli typically lodge 4 to 7 cm from the vessel’s origin at a point of anatomic narrowing such as the takeoff of a major arterial branch. More than 50% of SMA emboli are found immediately distal to the origin of the middle colic artery. Risk factors for mesenteric arterial emboli include coronary artery disease, valvular heart disease, and arrhythmias—in particular, atrial fibrillation. A recent review of autopsy findings of thromboembolic occlusion of the SMA found a common association with acute myocardial infarction, cardiac thrombi, and synchronous emboli to other organs. Risk factors are listed in **Box 90-3**. Recognition of these contributing factors is important to improve early diagnosis of this disease.

**Mesenteric Arterial Thrombosis**

The SMA, which originates from the ventral surface of the abdominal aorta at a 45-degree angle, commonly is narrowed by atherosclerosis. This is the most common site for thrombus formation in the mesenteric circulation. In contrast with arterial embolism, the more proximal nature of thrombus formation results in greater visceral damage and a less favorable prognosis. SMA thrombosis usually occurs in patients with chronic, severe visceral atherosclerosis. As many as 50% of these patients give a history of “abdominal angina,” or abdominal pain after meals. Thus, risk factors associated with mesenteric arterial thrombosis include older age, diffuse atherosclerosis (coronary, cerebral, or peripheral vascular disease), and hypertension.

**Nonocclusive Mesenteric Ischemia**

Nonocclusive mesenteric ischemia has been defined only in the last 50 years, as intraoperative and postmortem examinations have revealed ischemic bowel without obvious vascular obstruction. The pathogenesis of nonocclusive mesenteric ischemia is multifactorial, but a common pathway involves mesenteric vasoconstriction, usually in response to low-flow states associated with decreased cardiac output or the administration of vasoactive medications. Factors contributing to the development of nonocclusive mesenteric ischemia include hypotension, which may be associated with many systemic diseases, and splanchnic vasoconstriction from various medications. Nonocclusive mesenteric ischemia is seen in patients of all ages and often develops during hospitalization for other medical or surgical problems.

**Mesenteric Venous Thrombosis**

Mesenteric venous thrombosis is the least common cause of acute mesenteric ischemia. It occurs in a younger population.
of patients, and the mortality rate is lower than that associated with other causes, ranging from 20 to 50%.

Mesenteric venous thrombosis rarely can be a primary diagnosis, but it often occurs in association with an underlying medical condition, including hypercoagulable states, inflammatory processes within the abdomen, local trauma, and conditions associated with relative venous stasis, including oral contraceptive use and inflammatory bowel disease. Historically, up to 60% of patients with mesenteric venous thrombosis have a history of peripheral deep vein thrombosis.

**Clinical Features**

**History.** The clinical findings associated with acute mesenteric ischemia, regardless of the cause of the vascular compromise, are fairly nonspecific. Nonetheless, the presentation is sufficiently characteristic that acute mesenteric ischemia should be considered in the population of patients at risk: In patients older than 50 years of age with any of the previously discussed risk factors for mesenteric ischemia, the sudden onset of abdominal pain severe enough to warrant medical attention and more than 2 hours in duration is highly suggestive of acute mesenteric ischemia.

On initial presentation, the patient with acute mesenteric ischemia typically complains of severe, poorly localized, colicky abdominal pain. Associated symptoms and signs may include nausea, vomiting, and frequent bowel movements as the bowel attempts to empty itself. The most consistent finding is pain that is out of proportion to the physical findings. This characteristic finding is noted because only visceral structures are initially ischemic, and the parietal peritoneum is spared. Mesenteric ischemia also can be more subacute in its presentation, with the insidious onset of less severe and vague abdominal pain, abdominal distention, and occult gastrointestinal bleeding.

**Physical Examination.** In the early phases of mesenteric ischemia, physical examination findings may be nondiagnostic. As the disease process continues, abdominal distention develops and palpation reveals diffuse abdominal tenderness without guarding. Transmural intestinal injury leads to peritoneal signs (involuntary guarding and rebound tenderness). Late in the ischemic episode, the abdomen is grossly distended, with absence of bowel sounds and exquisite tenderness to palpation. Heme-positive stool is noted in 25% of patients and often is a relatively late finding.

**Complications.** Delays in diagnosis permit progression of the disease process and the development of transmural intestinal ischemia, with its correspondingly high associated morbidity and mortality rates. Even with early diagnosis and aggressive management, however, a complicated course is to be expected. Secondary reperfusion injury is common, and bowel initially believed to be viable at the time of operation may become ischemic and infarct in the postoperative period. Other postoperative complications include wound infections, intra-abdominal abscesses, sepsis, and pneumonia. This population of patients also is at risk for many life-threatening complications (including myocardial infarction, pulmonary embolism, and renal failure) because of significant concurrent illness.

**Diagnostic Strategies**

Routine laboratory and standard radiographic evaluations usually are not helpful in the diagnosis of mesenteric ischemia. An increase in the peripheral white blood cell count is a common but nonspecific finding, and although a normal count makes the diagnosis of acute intestinal ischemia less likely, it does not exclude the diagnosis. Hemoconcentration, metabolic acidosis with base deficit, and hyperamylasemia are present in more than one half of the cases of acute mesenteric ischemia but likewise are nonspecific findings. A significant emphasis has been placed on the role of serum lactate level determination in detection of ischemia, but a consensus regarding the utility of this test has yet to be reached. The sensitivity of this serum marker is high, approaching 100% when bowel infarction is present, but it has a disappointing specificity. A retrospective review of data on preoperative assessment for mesenteric ischemia noted an elevated serum lactate level at the time of diagnosis to be most useful as a significant predictor of mortality and suggested that the presence of unexplained acidosis in patients at risk should prompt a search for reversible causes of mesenteric ischemia. Levels of the seromuscular enzyme creatine kinase (CK) rise 3 to 4 hours after vascular occlusion, but the CK assay has limited specificity and sensitivity. Other seromuscular enzymes (lactate dehydrogenase, aspartate transaminase) and mucosal enzymes (alkaline phosphatase) are even less sensitive and specific than CK. Although it also has been suggested that a negative result on D-dimer assay may be useful for the exclusion of suspected mesenteric artery occlusion, further evaluation of this laboratory screen needs to be accomplished before widespread application.

The first radiologic examination that should be done in a patient with suspected mesenteric ischemia is a plain abdominal radiograph series (supine and upright) to rule out bowel obstruction or presence of free air. Plain radiographs most often are normal in appearance in the presence of acute mesenteric vascular compromise. By the time any changes characteristic of acute intestinal ischemia are apparent, transmural damage has already taken place. Subtle signs of acute mesenteric ischemia on plain abdominal radiographs include adynamic ileus, distended air-filled loops of bowel, and bowel wall thickening from submucosal edema or hemorrhage (Fig. 90-2). In advanced stages of ischemia, pneumatosis of the
bowel wall may be detected as intraluminal gas dissects into the submucosa.40 Another late, and often preterminal, sign of necrotic bowel is the presence of gas within the portal venous system. Further radiographic examinations should be selected judiciously. Intraluminal barium contrast evaluations are contraindicated because residual contrast material can limit visualization of the mesenteric vasculature during diagnostic angiography. Duplex ultrasonography may be of some benefit in visualizing blood flow in the SMA and celiac axis. Unfortunately, many patients suspected of having mesenteric ischemia often have dilated, air-filled loops of bowel, which makes ultrasonography extremely difficult.

Because of the availability, improved quality, and speed of CT, this radiologic test often is used for assessing undiagnosed abdominal pain in high-risk patients. In the setting of intestinal ischemia, a CT scan is capable of demonstrating edema of the bowel wall and mesentery, abnormal gas patterns, presence of intramural gas, ascites, and, occasionally, direct evidence of mesenteric venous thrombosis. The diagnosis of acute mesenteric ischemia often is made by CT imaging, reflecting the prevalence of this test in the evaluation of abdominal pain. Finally, an important consideration is that, as with plain radiography, a significant percentage of patients may have normal or nonspecific CT findings, so the diagnosis of mesenteric ischemia cannot be ruled out on the basis of normal findings on this study.

Angiography remains the “gold standard” modality for the diagnosis of mesenteric ischemia and is unique among imaging techniques in that it may assist with both diagnosis and therapy. Preoperative angiography is useful in the diagnosis of either mesenteric artery embolus or thrombus. It allows identification of the site and type of occlusion as well as evaluation of the splanchnic circulation, thus facilitating plans for prompt revascularization. Thrombosis of the SMA typically reveals an occlusion just distal to the origin of the vessel. In addition, angiography provides a definitive diagnosis of nonocclusive mesenteric ischemia. Arteriographic signs of nonocclusive disease include diffuse or focal tapering of mesenteric arterial branches, alternating segments of narrowing and dilatation of intestinal branches (“sausage sign”), poor intramural vessel filling, and mesenteric arcade vasospasm. Broad criteria for selection of patients must be used if early diagnosis and effective intervention are to be possible. Therefore, a significant number of “negative” angiograms should be accepted.

Helical CT scanning and CT angiography have progressed significantly in recent years and now offer reasonable alternatives to catheter angiography. Helical CT angiography should be considered the primary diagnostic modality for patients in whom clinical suspicion for mesenteric ischemia is high.41,42 Conventional catheter angiography is reserved for equivocal cases of noninvasive imaging and also can be used for transcatheter therapeutic techniques.

**Differential Considerations**

Mesenteric ischemia occurs most often in patients older than 50 years, but the diagnosis should be considered in all patients, regardless of age, who experience sudden onset of severe abdominal pain. The severe and colicky nature of the pain also may suggest cholecystitis, peptic ulcer disease, perforation of bowel, nephrolithiasis, diverticulitis, or bowel obstruction. The significant pain, often out of proportion to the physical findings, also may suggest the possibility of pancreatitis and abdominal aortic aneurysm rupture. The urgency of efficiently identifying acute mesenteric ischemia would recommend that this diagnosis be considered in a large population of patients, particularly in patients at risk because of underlying illness or chronic medical therapy that produces vasoconstriction. In practice, the diagnosis of acute mesenteric ischemia often is made after other disorders have been excluded.

Management and Disposition

Early diagnosis achieved by aggressive use of angiography remains the key to a successful outcome. Therapeutic intervention should take place as soon as the diagnosis of acute mesenteric ischemia is made if tissue salvage is to be maximized and mortality minimized.

Initial resuscitative efforts should include correction of hypovolemia and hypotension as well as any accompanying metabolic abnormalities. In the population of patients at risk for mesenteric ischemia, successful resuscitation may require invasive hemodynamic monitoring. Control of arrhythmias, congestive heart failure, and other factors contributing to relative hypoperfusion of the bowel is a priority. Medications with vasoconstrictive properties should be discontinued immediately. If vasopressors must be used to support blood pressure, the lowest possible dose should be infused, and α-agonists should be avoided, with inotropes being the preferred agents. Enteral decompression by nasogastric tube placement is recommended. Broad-spectrum antibiotic therapy that provides coverage for bowel flora should be initiated early, particularly when surgery is anticipated.

When the patient’s condition is stabilized, routine laboratory and plain radiographic examinations can be performed to exclude other, more common causes of abdominal pain. If an expeditious evaluation does not reveal an alternative diagnosis, angiography should be performed. Even when the decision to operate has been made on clinical grounds, preoperative radiologic studies, including some form of angiography, may improve management of the patient at laparotomy. In addition, when the diagnosis of acute mesenteric arterial compromise is confirmed, an infusion of papaverine through the angiography catheter directly into the SMA reduces or eliminates vasoconstriction. Papaverine is a potent inhibitor of phosphodiesterase, the enzyme necessary for degradation of cyclic adenosine monophosphate (cAMP). Increased cAMP levels cause vascular smooth muscle relaxation and relief of vasoconstriction. Because papaverine is 90% metabolized by the liver on its first pass, few if any systemic effects are noted during its use. Dosing consists of delivery of a 60-mg bolus into the SMA, followed by continuous infusion of 30 to 60 mg/hour at a concentration of 1 mg/mL. Use of this vasodilator in both nonocclusive and occlusive forms of mesenteric ischemia has improved survival.

The surgical management of acute mesenteric ischemia is both challenging and controversial. Treatment principles range from pharmacologic manipulation without operation to revascularization procedures to bowel resection. The underlying cause of intestinal hypoperfusion often is not amenable to surgical correction, as with mesenteric venous occlusion and nonocclusive disease, and the role of operative intervention may be limited to resection of already infarcted bowel. If a revascularization procedure is to be undertaken in the presence of arterial occlusive disease, it is completed before any evaluation of bowel viability is performed. The reasoning behind this therapeutic sequence is that bowel that initially appears irreversibly damaged may exhibit significant recovery on restoration of blood flow. Obviously necrotic bowel is resected, but in the presence of extensive ischemic damage, the surgeon may choose to leave bowel of questionable viability in place and to reevaluate its viability during a subsequent operation.44 This “second-look” operation, typically performed 12 to 24 hours after the initial procedure, may permit a more limited resection.

Percutaneous transluminal angioplasty has been described for both acute and chronic mesenteric ischemia from thrombosis of the SMA. In the acute setting, it appears to be associated with an increased risk of recurrence and potential for extensive bowel loss. With chronic intestinal ischemia, particularly in elderly patients who are poor surgical candidates, mesenteric angioplasty is a good option, with complete symptomatic improvement and continued relief of symptoms during follow-up observed in a majority of patients.

Intra-arterial infusion into the SMA of thrombolytic agents has been used successfully for mesenteric ischemia after acute embolism, but only on a limited basis. The patients in the reported series were selected with emboli confirmed by angiography, with no peritoneal signs and no abdominal radiographic abnormalities including ileus. Close monitoring and frequent clinical reassessment, as well as serial angiograms, are necessary after the thrombolytic infusion. The main drawbacks to the use of thrombolytic agents are the difficulty in assessing bowel viability without laparotomy, the possible time delay of 12 to 18 hours before clot resolution, and the potential for clot fragmentation with involvement of more distal branches less amenable to surgical revascularization.

In patients surviving the initial episode of acute mesenteric ischemia, recurrent thrombosis is a potential problem requiring long-term anticoagulation. Warfarin (Coumadin) is started after mesenteric arterial embolism and mesenteric venous thrombosis. Antiplatelet therapy is begun after mesenteric arterial thrombosis and nonocclusive mesenteric ischemia. The 2-year mortality rate after mesenteric ischemia is as high as 70%. This grave prognosis, however, is related mainly to cardiovascular comorbidity, rather than to recurrent mesenteric ischemic events.

### KEY CONCEPTS

- Four separate acute mesenteric ischemia syndromes are recognized. A majority of cases are caused by embolic occlusion of the SMA. The remainder are due to SMA thrombosis, venous thrombosis, and nonocclusive arterial ischemia. Each of the syndromes has a specific set of risk factors or associated medical conditions that are helpful in differentiating one from another.
- The diagnosis of acute mesenteric ischemia may be suggested by pain out of proportion to examination findings, heme-positive stool, elevated serum lactate levels, and classic findings on plain film or CT scan, but none of these provide enough sensitivity to ensure recognition of this entity before bowel infarction occurs.
- An aggressive approach to diagnosis and management, including early use of angiography, has provided some improvement in the prognosis for acute mesenteric ischemia, although the mortality rate for this disease is still greater than 50%.

CHAPTER 91 Acute Appendicitis

Jeannette M. Wolfe and Philip L. Henneman

■ PERSPECTIVE

Appendicitis is a common condition requiring emergency surgery. Approximately 7% of people will experience acute appendicitis during their lifetime. Most cases occur in adolescents and young adults, with a slightly higher incidence in men than in women.1,2

Historically, the earliest evidence of appendicitis is suggested by the presence of right lower quadrant adhesions in an Egyptian mummy from the Byzantine era. In 1492, Leonardo da Vinci drew pictures of the colon and the appendix, referring to the latter structure as an "orechio," which literally means "ear." Claudius Amyand removed the first appendix incidentally in 1735 during the repair of a scrotal hernia in an 11-year-old boy. The appendix had perforated, and a cutaneous fecal-draining fistula had developed.3 The half-hour operation was done without anesthesia, and the boy fully recovered. In the early 1800s during the Lewis and Clark expedition, the only death during the trip was that of Charles Floyd, who is thought to have died from a ruptured appendix.4

In 1880 in Europe, Lawson Tait performed the first successful planned appendectomy by removing a gangrenous appendix from a 17-year-old girl. Six years later, Reginald Fitz, a pathologist, coined the term appendicitis when he presented his classic paper at the first meeting of the Association of American Physicians. Fitz correctly described many of the pathophysiologic changes associated with appendicitis and advocated early surgery. Three years later, Charles McBurney described a point "determined by the pressure of one finger" between "one and a half and two inches from the anterior spinous process" that, when palpated, was associated with maximal discomfort in patients with acute appendicitis (McBurney’s point). The general acceptance that appendicitis was a surgical disease did not come until several decades later. Early surgical intervention became popular in the early 1900s around the time that King Edward VII was found to have a perforated appendix and was operated on days before his coronation.5

■ PRINCIPLES OF DISEASE: PATHOPHYSIOLOGY

The appendix is a hollow, muscular, closed-ended tube arising from the posterior medial surface of the cecum, approximately 3 cm below the ileocecal valve. Its average length is approximately 10 cm, and its normal capacity is 0.1 to 0.3 mL. The role of the appendix in human physiology is unclear, but some recent studies on biofilms suggest that the appendix may act as a repository for commensal bacteria that inoculate the large bowel and protect it against pathogens.6 Innervation of the appendix is derived from sympathetic and vagus nerves from the superior mesenteric plexus. Afferent fibers that conduct visceral pain from the appendix accompany the sympathetic nerves and enter the spinal cord at the level of the tenth thoracic segment. This allows referral of pain to the umbilical area.

In a majority of affected patients, appendicitis is due to an acute obstruction of the appendiceal lumen. The obstruction often is from an appendicolith but also can be caused by a calculus, tumor, parasite, or enlarged lymph node. Of historical note, one of the more common causes of acute appendicitis from foreign objects in the early 19th century was ingestion of lead shells buried in quail flesh.7 More recently, a lumen obstruction from a swallowed tongue stud has been reported.8

After acute obstruction, intraluminal pressures rise and mucosal secretions are unable to drain. The resulting distention stimulates visceral afferent pathways and is perceived as a dull, poorly localized pain. Abdominal cramping may occur as a result of hyperperistalsis. Next, ulceration and ischemia develop as the intraluminal pressure exceeds the venous pressure and bacteria and polymorphonuclear cells begin to invade the appendiceal wall. The appendix may appear grossly normal at this time, with evidence of pathology apparent only by microscopic examination. With time, the appendix becomes swollen, and factors elaborated in the pathologic process begin to irritate surrounding structures, including the peritoneal wall. The pain now becomes more localized to the right lower quadrant. If swelling does not abate, hypoxia leads to gangrene (presence of necrosis) and, ultimately, perforation through the appendiceal serosal layer. This can lead to abscess formation or diffuse peritonitis. The time required for the appendix to perforate is highly variable (and controversial—some experts believe that unless a virulent organism or genetic predisposition exists, many cases will spontaneously resolve), but perforation usually occurs within 24 to 36 hours. Elderly patients may be more prone to earlier perforation because of anatomic changes in the appendix associated with aging, such as a narrowed appendiceal lumen, thinner mucosal lining, decreased lymphoid tissue, and atherosclerosis.9

In approximately one third of cases, no direct cause of obstruction is noted. In these cases, it is surmised that inflammation is caused by viral, bacterial, or parasitic infection with subsequent mucosal ulceration or lymphoid hyperplasia.2
Abdominal CLINICAL PART Section Five Gastrointestinal System

1194

positive likelihood ratio for identifying patients with appendicitis. Certain findings have a high sensitivity in diagnosing acute peritonitis. A positive cough sign has been found to be 80 to 95% sensitive in diagnosing acute peritonitis. Both of these findings reflect the tensing of the abdominal wall muscle to protect the underlying bowel.

Rovsing sign is present when tenderness is referred to the right lower quadrant with palpation of the left lower quadrant. The psoas sign is the increase in pain when the psoas muscle is stretched as the patient is asked to extend the hip. The obturator sign is the elicitation of pain as the hip is flexed and externally rotated.

Rebound tenderness to palpation is a late finding in patients with appendicitis and is usually noted after the appendix is significantly inflamed or ruptured. Rebound tenderness is detected by gradually pressing over the area of tenderness for 5 to 10 seconds and then quickly withdrawing the hand to just above the skin level. A positive response is when the patient reports increased pain as the hand is removed. Patients with rebound tenderness are very uncomfortable with this maneuver, and it should not be repeated unnecessarily. The sensitivity and specificity of rebound tenderness in diagnosing acute appendicitis range from 63 to 82% and from 69 to 90%, respectively. The presence of peritoneal irritation also can be elicited by other maneuvers that cause the visceral and parietal peritoneum to rub against each other, such as having the patient cough while observing for evidence of acute discomfort. A positive cough sign has been found to be 80 to 95% sensitive in diagnosing acute peritonitis.

Isolated rectal tenderness rarely may be the only site of localized pain in patients with a low-lying or retrocecal appendix. In general, however, rectal tenderness has a very limited diagnostic value, especially if concurrent right lower quadrant pain and tenderness are present. Although a single rectal exam may provide other important information, such as the discovery of a rectal mass or occult blood, multiple exams are not justified.

Although any of the foregoing signs may be present in patients with acute appendicitis, certain findings have a high positive likelihood ratio for identifying patients with appendicitis. These include right lower quadrant pain, rigidity, and migration of initial periumbilical pain to the right lower quadrant. Conversely, the presence of pain for more than 48 hours, a history of previous episodes of similar pain, the lack of migration and of right lower quadrant pain, and the lack of worsening pain with movement or cough make appendicitis less likely. A similar review of data on children with appendicitis concluded that fever and rebound tenderness were the most common associated findings. Vital signs often are normal, particularly early in the clinical course. A low-grade fever is present in approximately 15% of patients; this increases to approximately 40% if perforation has occurred.

Special Considerations

Children

Acute appendicitis in young children often is diagnosed after perforation has occurred. Many common childhood illnesses are associated with nausea, anorexia, and vomiting, and young children may have difficulty communicating their discomfort. Anatomically, children have a thinner appendiceal wall and a less developed omentum, which may predispose them to perforation and diffuse peritonitis.

Women

The diagnosis of acute appendicitis in women of childbearing age can be particularly challenging. Before the advent of imaging, as many as 45% of women with symptoms suggestive of appendicitis had a normal appendix at surgery, and as many as one third of women with true appendicitis were initially misdiagnosed. Gynecologic disease can easily masquerade as appendicitis because of the close proximity of the appendix to the right ovary and fallopian tube and the uterus. Findings that may be more suggestive of abdominal pain of gynecologic origin are listed in Table 91-1. Of note, although cervical motion tenderness is more common in patients with pelvic inflammatory disease, it may be present in up to one fourth of women with appendicitis. Because accurately diagnosing appendicitis in women is difficult, the use of ancillary imaging should be strongly considered.

Pregnant Women

In pregnant women, the overall risk for the development of appendicitis is similar to that in the general population. Appendicitis appears to occur slightly more often in the second trimester than in the other two, for unknown reasons. The

Complications may also occur in pregnant women. The complication rate after the removal of a normal or acutely inflamed appendix is approximately 3%, but this increases by three- to four-fold if perforation occurs. The most common complication is infection. Localized wound infection occurs in approximately 2 to 7%, and deep intra-abdominal abscess occurs in 0.8 to 2%, with the higher percentages representing cases in which perforation had occurred. Other complications include a prolonged ileus, small bowel obstruction, pneumonia, and urinary retention and infection. In young women, perforation may cause obstruction of the fallopian tubes with subsequent fertility problems, although recent studies suggest that this sequela is not as prevalent as was once believed. Pregnant patients with appendicitis have an increased risk of premature labor (15 to 45%) and fetal death. The mortality rate for uncomplicated appendicitis is less than 0.1% but increases to 3 to 4% with perforation in patients with comorbid illness or advanced age. Although reported perforation rates vary significantly, the overall average is approximately 20 to 30%. This increases greatly at the extremes of age. Elderly persons have perforation rates as high as 60%, and children younger than 3 years of age can have perforation rates as high as 80 to 90%.

The identification of factors that may increase a patient’s risk for perforation is evolving. The traditional belief has been that the natural course of appendicitis is inflammation that, if surgery is delayed, ultimately progresses to necrosis and perforation. Many experts now feel that in most patients, the natural course of appendicitis is spontaneous resolution without perforation. This view is supported by general autopsy reports from the presurgical era showing that in up to one third of cases not previously diagnosed, evidence of periappendiceal scarring was present, and by studies that report successful resolution of early appendicitis with nonoperative management. It is hypothesized that a subset of the population is genetically predisposed to perforation by a characteristic early aggressive and exaggerated inflammatory response. The evidence for such a predisposition is the relatively consistent population perforation rates, even with the advent of increased imaging and earlier diagnosis. In most patients so affected, perforation of the appendix occurs before medical evaluation, and hospital delays in operative management rarely appear to increase perforation rates.

### Diagnostic Strategies

#### Laboratory Testing

**Leukocyte Count**

Approximately 80 to 90% of patients with acute appendicitis will have an elevated white blood cell (WBC) count above 10,000/mm³. Unfortunately, the leukocyte count is nonspecific and often is elevated with other causes of abdominal pain.

**C-reactive Protein**

A meta-analysis suggests that the overall sensitivity of C-reactive protein is approximately 62% and its specificity is 66%. Accordingly, its usefulness as a diagnostic tool in patients with appendicitis is limited.

**Urinalysis**

A urinalysis is helpful in differentiating urinary tract disease from acute appendicitis and is suggested in all patients. Mild sterile pyuria may be seen if the appendix is irritating the ureter. Significant pyuria (i.e., presence of more than 20 WBCs per high-power field) is highly suggestive of urinary tract pathology.

**Pregnancy Test**

A pregnancy test should be performed in all women of childbearing age, because a positive result broadly expands the scope of the differential diagnosis for right lower quadrant pain.

#### Diagnostic Scores

Some retrospective studies have shown a benefit for use of diagnostic scoring systems for appendicitis that assign a numerical value to different aspects of the history and physical exam. Of note, however, these scoring systems yield inconsistent results when prospectively evaluated and appear to be particularly inaccurate when applied to female patients.

#### Imaging Studies

**Plain Radiography**

Plain radiography is not useful in diagnosing appendicitis owing to its very low sensitivity and specificity and is not recommended in the evaluation of appendicitis unless there is a significant concern of bowel obstruction, free air, or pneumonia.

**Barium Enema**

Barium enema has a sensitivity of approximately 80 to 90% for detecting appendicitis, and the diagnosis is essentially ruled out if the entire appendix is filled with contrast. Unfortunately, a normal appendiceal lumen often is not visualized with this technique. Barium enema is most helpful when other colon pathologic processes are high on the list of considerations in the differential diagnosis.
The use of nuclear imaging with tagged WBCs has been well studied as a diagnostic tool for acute appendicitis. The sensitivity of nuclear scans depends on the radiolabel used, and reported values range between 88% and 98%. The overall usefulness of these scans is limited because of poor specificity—any process causing inflammatory changes in the lower abdomen can lead to a false-positive result.

**Ultrasonography**

Graded-compression ultrasound imaging has been prospectively shown to improve the clinical accuracy of the diagnosis of acute appendicitis. The reported sensitivity and specificity of ultrasound imaging for acute appendicitis in most studies are 75 to 90% and 85% to 95%, respectively. Some recent advances in ultrasound techniques have been described. One group of investigators reported an astonishing 98% rate for visualization (compared with the often cited 2 to 45%) of the appendix by adding simple maneuvers that repositioned this structure. Similarly, small studies using contrast-enhanced Doppler or harmonic waves (which allow for better resolution) show promise of higher sensitivities while sparing the patient radiation exposure.

On ultrasound examination, a noncompressible appendix with a diameter greater than 6 to 7 mm is considered diagnostic for appendicitis. Ultrasonography is inexpensive, requires no patient exposure to radiation or dye, adds no extra time for contrast filling, and has had long-standing success in diagnosing pelvic pathology in women. It also allows correlation of the patient’s pain with direct visualization of underlying abdominal contents. The major disadvantage of ultrasonography is that visualization of the appendix—normal or abnormal—is operator-dependent, and the technique can be especially difficult if the patient is obese, has strictures from previous surgeries, or has a retrocecal appendix. A diagnostic ultrasound study also becomes more difficult to achieve after the appendix has perforated, and patients with significant right lower quadrant pain may not tolerate the graded compression.

Ultrasound findings suggestive of appendicitis have a very high positive predictive value (approximately 90%). Absence of abnormality on the ultrasound study, however, is not helpful unless the appendix is clearly visualized or alternative pathology is identified. Accordingly, with negative ultrasound findings, either in-hospital observation or a CT scan is indicated if the patient’s symptoms have not abated.

**Computed Tomography**

Abdominal pelvic CT scanning has been prospectively studied and shown to improve the clinical accuracy of the diagnosis of appendicitis. CT findings individually suggestive of appendicitis include an enlarged appendix (diameter greater than 6 mm), pericecal inflammation, the presence of an appendicolith (Fig. 91-1), and a periappendiceal phlegmon or abscess (Fig. 91-2). The sensitivity (87 to 100%) and specificity (89 to 98%) of CT scan vary by study and technique and by how investigators categorize inconclusive scans in their statistical analyses.

Of the different CT techniques, thin-cut, helical CT with rectal contrast appears to be the most sensitive, with sensitivity rates as high as 98%. Use of rectal contrast confers a number of advantages: it may be better tolerated in nauseated patients; there is no delay in scanning due to contrast transit time; and more consistent cecal opacification is obtained, which aids in scan interpretation. Although rectal contrast may not be conceptually or practically acceptable to some patients, at least in one study patient discomfort and satisfaction rates were similar regardless of type of contrast received.

Oral contrast abdominal pelvic CT is an alternative choice but requires a 60- to 90-minute delay after contrast administration for distal small bowel opacification and may be poorly tolerated in the patient with nausea or an ileus. A novel way to decrease transit time is to add polyethylene glycol to the oral contrast; in one study, this allowed good cecal opacification by 1 hour after ingestion.

Although certain institutions have published high sensitivity and specificity rates with noncontrast CT scans, these
findings have not been reproducible in other settings.\textsuperscript{50,51} Two recent studies found a 20 to 25% rate for inconclusive scan interpretation when no contrast was used.\textsuperscript{52,53} Periappendiceal fat streaking can easily be missed on a noncontrast CT scan obtained in thin patients or children.

Intravenous contrast may help diagnose very early appendicitis by enhancing appendiceal wall inflammation, but in most instances it adds little additional information and increases the risk of adverse dye reaction.

CT scanning has some advantages over ultrasound in the diagnostic evaluation of appendicitis. With enteric contrast CT, the appendix usually can be visualized, the technique is standardized, and alternative pathology often is identified. An added benefit is that the identification of CT signs of appendicitis is relatively straightforward and can be easily learned. This is an important consideration because the initial interpretation of the CT usually dictates patient disposition, and in an academic teaching center, this scan often may be read by a junior radiology resident after hours.\textsuperscript{54}

The biggest disadvantages of CT scanning are the radiation exposure and the expense. A routine full abdominal and pelvic CT study results in about 10 millisieverts of radiation exposure, which theoretically is carcinogenic. From analysis of data for World War II atomic bomb survivors, it has been suggested that the radiation from a single abdominal CT scan could cause a fatal cancer in 1 of every 500 children scanned.\textsuperscript{55} Radiation exposure can be decreased by doing a focused 15-cm scan limited to the iliac crest and pelvis and by size-adjusting the scanner.

Finally, CT is not 100% accurate. Overall, approximately 5 to 10% of CT scans are considered inconclusive for appendicitis—for example, the appendix diameter may be enlarged but without wall thickening, or the appendix may not be visualized although surrounding fat streaking is evident. Care should be taken not to label these studies as “negative,” because approximately 30% of patients with such equivocal findings will have histologic confirmation of appendicitis.\textsuperscript{56}

In general, even patients with a true negative result on the CT scan should be explicitly told to return for reevaluation if their symptoms worsen or do not resolve in the next 24 to 36 hours. Such follow-up is particularly important in patients evaluated within the first few hours of symptoms, because early appendicitis may be missed on the initial CT scan.\textsuperscript{57}

### Magnetic Resonance Imaging

MRI is emerging as a useful tool in the evaluation of suspected appendicitis, with reported sensitivity similar to that for CT scan. Access to MRI is currently limited in most EDs, however, so its use often is confined to the pregnant patient with indeterminate ultrasound findings as an alternative to CT.\textsuperscript{58,61}

### Laparoscopy

Laparoscopy can be performed for diagnosis or definitive treatment. Historically, its greatest advantage was in the clarification of the diagnosis of appendicitis versus gynecologic disease in young female patients. Because an enteric contrast CT scan can now usually visualize the appendix, the use of diagnostic laparoscopy with its anesthetic risks has decreased significantly.

### In-Hospital Observation

Despite the current increased tendency to pursue diagnostic imaging in patients with right lower quadrant abdominal pain, the recent literature suggests that most cases of appendicitis can still be accurately diagnosed by performing serial physical examinations.\textsuperscript{62,63} A review of studies using active inpatient observation in patients with an equivocal diagnosis of appendicitis found a negative appendectomy rate of approximately 6% without an increase in perforation rates.\textsuperscript{62}

#### Differential Diagnosis

The differential diagnosis for appendicitis includes essentially any pathologic process that can cause abdominal pain. The more common diseases that can mimic appendicitis are listed in Table 91-2. Of note, the diagnosis of gastroenteritis should be made with caution and only in patients with vomiting and diarrhea.

### Management

A strategy to manage patients with possible appendicitis is depicted in Figure 91-3. Patients should be kept on NPO (nil per os) status and undergo a complete physical examination, including a rectal and pelvic examination. Dehydrated patients should receive intravenous crystalloid fluids, parenteral antiemetics should be given to patients with nausea or vomiting, and patients with more than mild discomfort should be offered pain medication. Multiple studies have shown that giving opiate pain medicine to adults or children with signs of appendicitis does not mask important physical exam findings or impair surgical decision making.\textsuperscript{64,65} Furthermore, a recent meta-analysis concluded that any changes in the physical examination due to administration of medications did not appear significant enough to alter management in patients with acute abdominal pain.\textsuperscript{66} Depending on local surgical preference or institutional policy, surgical consultation before medication administration may be indicated, but only if it can be done in a timely fashion.

Controversy exists regarding when and how to best utilize advanced imaging techniques. Some experts have shown that CT scanning significantly decreases the rate of negative laparotomies, even in patients in whom clinical suspicion for appendicitis is high.\textsuperscript{67,68} Others feel that diagnostic imaging is overused and has not improved patient care.\textsuperscript{69,70} In any case, diagnostic imaging is likely to be most helpful if done in a select group of patients. After initial physical exam and laboratory tests, patients should be stratified by risk. Excessive imaging in patients who are at low risk for appendicitis will increase the frequency of false-positive results on relevant studies, because the prevalence of disease in this population is low. Patients may be considered to be at low risk if they have minimal physical findings and strong evidence for an alternative diagnosis, or if they have had multiple previous episodes of similar pain. The other distinct group of patients...
who may not benefit from imaging are patients who present within the first few hours of onset of symptoms. Imaging studies in these patients are more likely to yield false-negative results, and the “negative” scan may provide false reassurance. In both subsets, the best course of action probably is patient education about worsening signs of appendicitis, along with arrangements for immediate reevaluation if their symptoms progress, or for reexamination in 12 to 24 hours if they have not improved. Ideally, this conversation should be documented in the medical record.

Patients with “equivocal” signs of appendicitis should be considered for diagnostic testing or active observation. Surgical input by phone or formal consultation may be appropriate before imaging, depending on the preference of the consulting surgeon. “Equivocal” patients include most women (especially those of childbearing age). Historically, it has been very difficult to make an accurate diagnosis of appendicitis in women on clinical grounds alone, and negative laparotomy rates of 40 to 45% were common. Fortunately, imaging can dramatically decrease these rates and should be strongly considered in all women. Ultrasonography may be the most appropriate initial study if the history is strongly suggestive of gynecologic disease or if the pelvic examination reveals any abnormality. It also should be considered in very thin patients who have not previously had abdominal pelvic surgery; otherwise, an enteric contrast CT study is recommended.

If the patient is pregnant, ultrasound imaging is the first-line test to exclude other obstetric diagnoses. If the ultrasound findings are equivocal, MRI should be considered if it is readily available. Although CT is less desirable, owing to its considerable associated radiation exposure, after surgical and obstetric consultation, its use may still be justified when this drawback is balanced against the risks associated with potentially unnecessary anesthesia and surgery.

Other subgroups of “equivocal” patients are more difficult to define because of variable inclusion criteria among published studies. It appears reasonable that men and children with a clinical presentation suggestive of appendicitis but who lack at least one of its classic features (such as pain is new onset, migrates from periumbilical to right lower quadrant, and is associated with anorexia and tenderness) and have no clear alternative diagnosis be considered “equivocal.”

Ultrasonography often is recommended as the preferred initial imaging study in children with equivocal findings of appendicitis because it does not expose them to radiation. This is a significant consideration because children are particularly vulnerable to the risks of radiation owing to their increased cell division and longer life expectancy. A limited-cut helical CT study with enteric contrast (administered either rectally or orally) is an option in overweight children. If ultrasound imaging is chosen and the scan is interpreted as negative, a follow-up CT scan or admission for serial observation is indicated, unless the patient’s clinical status has improved.

Male patients with an equivocal presentation for appendicitis should be considered candidates for an enteric contrast CT examination (although US is a reasonable alternative for thin patients who can tolerate the US compression). Men with classic signs of appendicitis, however, are likely to have the disease more than 90% of the time, and imaging adds little to their workup. Although the current practice in some institutions has evolved such that CT is almost mandated before surgical involvement, a recent well-done study suggests otherwise: with a decision for surgical involvement before CT, 65% of male patients went to the operating room without a CT scan, with a 4% negative appendectomy rate. Emergency physicians should advocate institutional polices that prevent unnecessary radiation exposure in this group and in children with classic presentations; in these subsets, appendicitis is a clinical diagnosis.

Once the decision to operate has been made, prophylactic antibiotics should be given to provide coverage for gram-negative and anaerobic organisms; this strategy has been proved to decrease both superficial and deep postoperative
wound infections. Intravenous second-generation cephalosporins such as cefotetan or cefoxitin provide good coverage. In cases with a high likelihood of perforation, the traditional treatment has been a broad-spectrum triple antibiotic regimen; however, recent studies suggest that “single coverage” with a second-generation cephalosporin, mirapenam, or combination drug like piperillin and tazobactam provides similar coverage, with easier administration.76

The timing of surgical intervention has recently been challenged, with several studies suggesting that complication rates are not adversely affected if surgery is delayed until daylight hours.77 If this practice is to be adopted, it needs to be balanced by considerations including the condition of the individual patient and the potential for disrupting the morning operating room schedule and increasing the overall length of hospital stay.

The appendix can be surgically removed using either the traditional open technique or a laparoscopic approach. A Cochrane review of 45 randomized studies favored laparoscopic removal.78 The investigators concluded that laparoscopic appendix removal resulted in less frequent wound infections, less postoperative pain on day 1, shorter length of hospital stay, shorter time to return to normal activity, and decreased overall costs. Laparoscopy may be most helpful in female patients, in whom it allows inspection for pelvic pathology that may masquerade as acute appendicitis.

Some institutions have begun to develop extensive operative and postoperative guidelines for the care of patients with appendicitis.79,80 The use of these guidelines has decreased postoperative complications and costs and appears to be most helpful in the subgroup of patients with perforation.

For patients with evidence of obvious perforation and abscess formation, many surgeons prefer to drain the abscess nonoperatively and treat the condition with intravenous antibiotics and then perform an interval appendectomy 6 weeks later.81 Recently, it has even been suggested that the appendix may not have to be removed after successful abscess resolution.82

### DISPOSITION

If clinical suspicion for appendicitis is low, the patient may be sent home after extensive education has been provided and arrangements have been made for appropriate follow-up care. Discharged patients should be encouraged to start on a liquid diet and advance to solids if their symptoms abate.

Patients with abdominal pain of unclear etiology who require significant doses of opiates to control their pain should be considered for hospital admission.83 In addition, if follow-up cannot be arranged, if patient or family reliability is in question, or if a significant language or transportation barrier exists, hospitalization for observation should be considered.

---

**KEY CONCEPTS**

- Classic appendicitis is a clinical diagnosis.
- Patients with a low risk for appendicitis may be sent home with close follow-up and education about progressive symptoms.
- Patients with equivocal findings should undergo advanced diagnostic imaging or in-hospital serial examinations.
- Men and children with classic signs and symptoms of appendicitis should undergo prompt surgical evaluation, because imaging may be unnecessary.
- Ultrasound examination is an appropriate initial test in pregnant patients, in women with a clinical presentation suggestive of pelvic pathology, and in thin children and women.
- Helical CT with enteric contrast is considered the initial imaging study of choice in all male patients with equivocal signs of appendicitis and in female patients without findings suspicious for gynecologic disease (although US is a reasonable alternative for thin patients who can tolerate the US compression). Pain medication should be offered to all patients with suspected appendicitis. Antibiotics should be given preoperatively.

CHAPTER 92  Gastroenteritis

Sandy A. Craig and David K. Zich

BACKGROUND

Gastroenteritis is defined as an inflammation of the stomach or intestines resulting in some combination of nausea, vomiting, and diarrhea. Although most affected patients will prove to have an infectious cause for their symptoms, the clinician also must consider noninfectious causes of vomiting and diarrhea, which are considered in detail in Chapters 20 and 23, respectively.

Infectious gastroenteritis is associated with dozens of causative pathogens. Most of these organisms cause benign and self-limited illness, but in a few cases, morbidity may be significant, necessitating prompt diagnosis and treatment. Diagnostic testing should be targeted to those patients who have clinically significant illness or suspected reportable disease. It is neither feasible nor necessary to identify the specific pathogen during the emergency department (ED) evaluation. Instead, the clinician should classify the gastroenteritis as acute or chronic, based on readily available clinical information. This classification narrows the differential diagnosis considerably and is a valuable guide to further testing.

Acute gastroenteritis lasts less than 2 weeks. The vast majority of ED patients will have acute gastroenteritis, and viral and bacterial pathogens should be the primary considerations in the differential diagnosis. Chronic gastroenteritis persists longer than 2 weeks. In such cases, the possibility of a parasitic pathogen should be added to the differential diagnosis.

Invasive gastroenteritis is a clinical diagnosis made in the presence of signs or symptoms of intestinal mucosal invasion, such as fever, gross or occult blood in the stool, tenesmus, or abdominal pain. When invasive disease is suspected, further diagnostic testing is indicated. Patients with noninvasive gastroenteritis do not exhibit fever, produce bloody stools, or experience significant abdominal pain. Noninvasive gastroenteritis suggests the presence of a viral pathogen or toxin-producing bacteria. This illness typically is brief and self-limited, and diagnostic testing is not likely to be of benefit.

ACUTE INVASIVE BACTERIAL ENTERITIS

Potential pathogens in acute invasive bacterial enteritis are summarized in Table 92-1.

Campylobacter Enteritis

Epidemiology. Campylobacter is the most common documented cause of bacterial enteritis in developed countries. In Canada, where the disease is reportable, campylobacteriosis was found in 30.2 persons per 100,000 in 2004, compared with 16 cases of salmonellosis per 100,000 population.1 Most cases occur in children younger than 5 years of age or in male patients between the ages of 20 and 29 years, but people of all ages are affected. The disease is more common during the summer months. Opportunistic infections with Campylobacter species often are found in homosexual men or patients with acquired immunodeficiency syndrome (AIDS), even in the absence of symptoms of diarrhea or proctitis. Campylobacter species are a common cause of “backpacker’s diarrhea,” along with Giardia, both of which are frequently acquired by drinking from wilderness water sources.

Pathophysiology. Campylobacter organisms are small, spiral-shaped gram-negative bacteria. The most common species isolated are Campylobacter jejuni (94%), Campylobacter coli (1%), and Campylobacter fetus.1 Campylobacter cinaedi and Campylobacter fennelliae are isolated almost exclusively from homosexual men. Campylobacter species produce disease primarily by direct invasion of the colonic epithelium and may induce inflammatory changes that are endoscopically indistinguishable from inflammatory bowel disease.

Most infections are acquired by handling raw poultry or eating raw or undercooked poultry meat. The primary reservoirs for Campylobacter organisms are chickens, with more than one half of U.S. flocks silently infected and well over one half of the chicken in U.S. supermarkets contaminated.2 Other causes include consumption of tainted beef, pork, raw milk, or untreated water, or contact with infected pets and farm animals.1

Clinical Presentation. The incubation period for Campylobacter enteritis is approximately 2 to 5 days. Disease onset usually is rapid, with signs and symptoms of fever, cramping abdominal pain, and diarrhea. Constitutional symptoms of anorexia, malaise, myalgias, and headache are the rule, and some patients experience backache, arthralgias, and vomiting. The clinical picture can mimic that in acute appendicitis. Onset of diarrhea often lags 24 to 48 hours after the onset of fever and abdominal pain. Typically, the stools are loose and bile-colored but then become watery, grossly bloody, or melanotic approximately 40% of the time. Either gross or occult blood is found in the stool of 60 to 90% of patients with Campylobacter gastroenteritis. At the height of the illness, patients usually pass 8 to 10 stools or more per day.3

Most patients are well within a week or less; however, diarrhea can persist for weeks. Relapses are common although generally milder than the original episode. Fatalities are rare;
Epidemiologic Considerations.

UNTREATED Appendicitis/terminal ileitis-like syndrome; Family and cafeteria-type food poisoning

Strategies. Because the clinical presentation is

SOURCES/RISK FACTORS

High attack rates, summer months; Toxigenic watery diarrhea, followed by

Strains. One study of outpatients with

abdominal pain, occult blood, or hematochezia. In borderline

patients who present with acute enteritis associated with fever,

diagnosis of campylobacteriosis cannot be made on the basis

similar to that with other invasive bacterial pathogens, the

duration of campylobacteriosis is not made on the basis of
clinical presentation alone. Identification of the pathogen

will require stool culture; specimens should be obtained in

patients who present with acute enteritis associated with fever,

abdominal pain, occult blood, or hematochezia. In borderline
cases, starch methyl blue stain for fecal leukocytes is readily

available and may help identify those patients who are likely
to harbor an invasive pathogen. One study of outpatients

with acute diarrhea found that the presence of fecal leukocytes

(greater than 5 white blood cells per high-power field) was

associated with a likelihood ratio (LR) of 5.0 for the presence

of an invasive pathogen (95% confidence interval [CI], 2.9 to

6.0).

Blood culture results are rarely positive, so these studies

are not routinely indicated. Sigmoidoscopy reveals a nonspecific

inflammatory colitis, and Campylobacter infection must be

considered before a new diagnosis of inflammatory bowel
disease is made.

Differential Considerations. The differential diagnosis for

suspected campylobacteriosis includes all infections with organ-

isms that produce invasive diarrhea or fecal leukocytes,

particularly salmonellosis, shigellosis, yersiniosis, and Escher-

ichia coli O157:H7 infection.

Management. Empirical antibiotic therapy is not recom-

mended for otherwise healthy patients who present with acute

invasive diarrhea. (Travel-related diarrhea is an exception and

is discussed later on.) Initial treatment of invasive diarrhea

should focus on rehydration, and the decision to initiate anti-

biotic therapy should be deferred pending the result of stool

culture. Treatment with antibiotics is not needed for patients

who demonstrate clinical improvement by the time stool

culture results become available. For those who are not improv-

ing, antibiotic therapy does shorten the duration of campylo-

bacteriosis by approximately 1.3 days. Erythromycin 500 mg

twice a day for 5 days is the recommended first-line therapeu-
tic regimen. Azithromycin 500 mg daily for 3 days is acceptable

as well. Ciprofloxacin 500 mg twice a day can be used and was

previously the treatment of choice, but alarming resistance to

the fluoroquinolones has emerged, thought to be due mainly to

antibiotic use in the poultry industry. Roughly 10% of Campy-

lobactes strains are now resistant in the United States, and

greater than 80% resistance has been documented in Thai-
lant. Campylobacter organisms generally are resistant to trime-

thoprim-sulfamethoxazole (TMP-SMX) as well. Suggested

antibiotic regimens for treatment of diarrhea are listed in

Table 92-2. Relapses can occur, but the likelihood is decreased

with appropriate antibiotic treatment. Because Campylobacter

infection is an invasive enteritis, antimotility agents are not

recommended unless treatment with antibiotics also is given.

Complications of Campylobacter infection are rare. Cholecyst-

tis, pancreatitis, and massive gastrointestinal bleeding all have

been documented, as have meningitis, endocarditis, and osteomyelitis. In addition, a definite association has been

made with Guillain-Barré syndrome. Guillain-Barré syndrome

associated with Campylobacter infection tends to be more

severe than Guillain-Barré syndrome from other triggers and

can occur even with asymptomatic infections. Luckily, the

incidence is estimated at less than 1 per 1000 cases.

Salmonellosis

Epidemiology. Salmonella is the second most common cause of
documented bacterial enteritis in the United States, with 36,184 cases (a rate of 12.2 cases per 100,000 population)
reported in 2005. The actual number of cases is estimated to
be greater than 1.4 million annually. U.S. surveillance systems found a 12% decrease in documented Salmonella infections in
2005 compared with 1995. Enteritis caused by this organism affects people of all age groups but particularly children, with
those younger than 5 years of age accounting for 20% of
cases.

The Centers for Disease Control and Prevention (CDC) estimates 124 fatal cases in the United States each year.

Diagnostic Strategies. Because the clinical presentation is similar to that with other invasive bacterial pathogens, the diagnosis of campylobacteriosis cannot be made on the basis of clinical presentation alone. Identification of the pathogen will require stool culture; specimens should be obtained in patients who present with acute enteritis associated with fever, abdominal pain, occult blood, or hematochezia. In borderline cases, starch methyl blue stain for fecal leukocytes is readily available and may help identify those patients who are likely to harbor an invasive pathogen. One study of outpatients with acute diarrhea found that the presence of fecal leukocytes (greater than 5 white blood cells per high-power field) was associated with a likelihood ratio (LR) of 5.0 for the presence of an invasive pathogen (95% confidence interval [CI], 2.9 to 8.6). Blood culture results are rarely positive, so these studies are not routinely indicated. Sigmoidoscopy reveals a nonspecific inflammatory colitis, and Campylobacter infection must be considered before a new diagnosis of inflammatory bowel disease is made.

Differential Considerations. The differential diagnosis for suspected campylobacteriosis includes all infections with organisms that produce invasive diarrhea or fecal leukocytes, particularly salmonellosis, shigellosis, yersiniosis, and Escherichia coli O157:H7 infection.

Management. Empirical antibiotic therapy is not recommended for otherwise healthy patients who present with acute invasive diarrhea. (Travel-related diarrhea is an exception and is discussed later on.) Initial treatment of invasive diarrhea should focus on rehydration, and the decision to initiate antibiotic therapy should be deferred pending the result of stool culture. Treatment with antibiotics is not needed for patients who demonstrate clinical improvement by the time stool culture results become available. For those who are not improving, antibiotic therapy does shorten the duration of campylobacteriosis by approximately 1.3 days. Erythromycin 500 mg twice a day for 5 days is the recommended first-line therapeutic regimen. Azithromycin 500 mg daily for 3 days is acceptable as well. Ciprofloxacin 500 mg twice a day can be used and was previously the treatment of choice, but alarming resistance to the fluoroquinolones has emerged, thought to be due mainly to antibiotic use in the poultry industry. Roughly 10% of Campylobacter strains are now resistant in the United States, and greater than 80% resistance has been documented in Thailand. Campylobacter organisms generally are resistant to trimethoprim-sulfamethoxazole (TMP-SMX) as well. Suggested antibiotic regimens for treatment of diarrhea are listed in Table 92-2. Relapses can occur, but the likelihood is decreased with appropriate antibiotic treatment. Because Campylobacter infection is an invasive enteritis, antimotility agents are not recommended unless treatment with antibiotics also is given. Complications of Campylobacter infection are rare. Cholecystitis, pancreatitis, and massive gastrointestinal bleeding all have been documented, as have meningitis, endocarditis, and osteomyelitis. In addition, a definite association has been made with Guillain-Barré syndrome. Guillain-Barré syndrome associated with Campylobacter infection tends to be more severe than Guillain-Barré syndrome from other triggers and can occur even with asymptomatic infections. Luckily, the incidence is estimated at less than 1 per 1000 cases.

Salmonellosis

Epidemiology. Salmonella is the second most common cause of documented bacterial enteritis in the United States, with 36,184 cases (a rate of 12.2 cases per 100,000 population) reported in 2005. The actual number of cases is estimated to be greater than 1.4 million annually. U.S. surveillance systems found a 12% decrease in documented Salmonella infections in 2005 compared with 1995. Enteritis caused by this organism affects people of all age groups but particularly children, with those younger than 5 years of age accounting for 20% of cases.
Almost all Salmonella infections are acquired from ingestion of contaminated food or drink. Direct person-to-person transmission can occur, but most human infections are related to the vast reservoir of salmonellae in lower-order animals. Poultry products and beef constitute the most common sources of the vast reservoir of salmonellae. Poultry, such as turtles, snakes, and iguanas, have been responsible for outbreaks of salmonellosis.

Cooking contaminated foods decreases the possibility of infection but does not eliminate it. Salmonellae can survive cooking deep inside certain foods, where temperatures may not reach the lethal range. Very large outbreaks of Salmonella infection have been traced to contaminated, unbroken, grade A eggs. Although the organism is present in the uncracked egg, thorough cooking usually eradicates or reduces the inoculum to clinically insignificant levels.

Common raw egg–based sources of Salmonella infections include homemade hollandaise sauce, eggnog, Caesar salad dressing, ice cream, mayonnaise, tiramisu, cookie dough (often consumed unbaked), frosting, and French toast mix. Salmonella enterica subspp. enterica serovar Enteritidis (i.e., “S. Enteritidis”) is the species universally associated with egg-related infections. Patients convalescing from Salmonella-related enterocolitis and persons with asymptomatic infection may continue to excrete Salmonella organisms for weeks or months, thus serving as ongoing sources of infection.

Pathophysiology. Approximately 2000 Salmonella serotypes are known to cause human illness. Based on 2005 U.S. surveillance figures, the most common isolates are the S. enterica serovars Typhimurium (19%), Enteritidis (18%), Newport
Different *Salmonella* serotypes show marked variations in invasive potential and are associated with particular presentations. *S. enterica* serovar Typhi with enteric fever (typhoid fever), *S. enterica* serovar Cholerae-suis with septicemia, *S. Typhimurium* with acute gastroenteritis, and *S. Enteritidis* infections from grade A shell eggs.

Relatively large numbers of salmonellae must be ingested to produce illness. However, a carrier state can be induced with ingestion of 10 to 100 times fewer bacteria needed to induce carrier state relative to number needed to induce illness. In infants and adults with certain underlying diseases, a much smaller inoculum may produce illness. Decreased gastric acidity or an alteration of intestinal flora resulting from the administration of antibiotics can impressively reduce the size of the required inoculum.

Rates of invasive infection and disease severity are increased in infants, the elderly, and people with hemoglobinopathies such as sickle cell anemia, malignant neoplasms, or AIDS.

The CDC estimates that more than 500 fatal cases occur each year.

**Clinical Presentation.** Family outbreaks and sporadic cases are more common than large epidemics. Ingested salmonellae penetrate the intestinal mucosal cells and lodge in the lamina propria. After an incubation period of 8 to 48 hours, the typical patient with *Salmonella* gastroenteritis presents with fever, colicky abdominal pain, and loose, watery stools, occasionally containing mucus and blood. Nausea and vomiting are common but rarely are severe or protracted. Mild to moderate diffuse abdominal tenderness can be elicited in most patients, but occasionally severe tenderness and even rebound tenderness may be noted. Symptoms usually abate within 2 to 5 days, and recovery typically is uneventful. Sustained or intermittent bacteremia may occur, especially in those with sickle cell anemia, malignancy, or AIDS. Focal infections are identified in 10% of those with *Salmonella* bacteremia.

**Diagnostic Strategies.** The diagnosis of salmonellosis cannot be made on the basis of clinical presentation alone; stool cultures are needed for confirmation. Stool methylene blue staining for fecal leukocytes may help identify those patients who are likely to harbor an invasive pathogen. Blood culture results occasionally are positive, and samples should be obtained from severely ill or immunocompromised patients. The possibility of an underlying disease or immunodeficiency state should be considered in every patient with a severe *Salmonella* infection.

**Differential Considerations.** Family or communal outbreaks can suggest *Staphylococcus*-related food poisoning, but staphylococcal enteritis has a shorter incubation period, is not associated with fever, and produces the typical toxicogenic, noninvasive, diarrheal picture. Vomiting is also much more prominent in cases of staphylococcal food poisoning than in most cases of *Salmonella* infection. The differential diagnosis for salmonellosis includes all organisms that produce invasive diarrhea or fecal leukocytes, particularly campylobacteriosis, shigellosis, yersiniosis, and *Escherichia coli* O157:H7 infection.

**Management.** Empirical antibiotic therapy is not recommended for otherwise healthy patients who present with suspected *Salmonella* enteritis. Antibiotic therapy does not shorten the duration of the disease and may prolong the duration of the carrier state. Although unproven, antibiotic therapy is recommended for patients with severe colitis and for infants younger than 3 months of age, adults older than 50 years, and other groups at risk for severe disease. Persons who represent a public health risk also should be treated in an attempt to eradicate the carrier state and prevent spread of the organism. The choice of antibiotic should be based on sensitivities of the isolate. Any of the following antibiotic regimens typically is effective for outpatient management of *Salmonella* gastroenteritis: ciprofloxacin, 500 mg twice a day for 5 to 7 days; norfloxacin, 400 mg twice a day for 5 to 7 days; or azithromycin, 1 g by mouth and then 500 mg a day for the next 6 days. TMP-SMX also can be used if the organism is susceptible. Ciprofloxacin is effective in the treatment of chronic *S.* Typhi carriers. However, treatment with fluoroquinolones can actually prolong shedding of non-Typhi organisms. Patients requiring hospitalization are best treated with intravenous ceftriaxone until results of sensitivity studies become available.

Follow-up with the patient’s primary care physician should be arranged. Food handlers and health care personnel should not be allowed to work until the carrier state has been eradicated. Repeated stool cultures and further decisions regarding job or school situations will be required. Personal hygiene should be emphasized, because untreated patients may continue to shed infective organisms in the stool for weeks or even months. As with other invasive pathogens, the use of antimotility drugs alone is contraindicated. These drugs prolong fever and diarrhea, increase the incidence of bacteremia, and promote development of a carrier state in patients with *Salmonella* enteritis. However, administration of loperamide is safe when it is given concomitantly with an appropriate antibiotic.

Prevention of salmonellosis depends on adequate cooking and minimizing the time that foods are allowed to stand at room temperature to reduce the chance of bacterial growth to an infectious inoculum. Careful personal hygiene, including hand washing, also is important. *Salmonella* infection is a nationally notifiable disease (Box 92-1).

Although most patients recover fully without long-term sequelae, up to 30% (primarily adults) will experience transient reactive arthritis. Reiter’s syndrome, consisting of reactive arthritis, conjunctivitis, and urethritis, is a well-known complication and occurs in approximately 2% of patients.

*In the United States, additional reporting requirements may be mandated by state and territorial laws and regulations. Details on specific state reporting requirements are available from the Council of State and Territorial Epidemiologists (http://www.cste.org) and the Centers for Disease Control and Prevention (http://www.cdc.gov). From Centers for Disease Control and Prevention: Nationally Notifiable Infectious Diseases—United States, 2007, revised. Available at: http://www.cdc.gov/epo/dphsi/phs/infdis2007cthtm (accessed 2007 November 8).
Shigellosis

Epidemiology. Shigellosis, or bacillary dysentery, is worldwide in distribution and particularly common in countries lacking effective sanitation. In the United States, a total of 10,484 cases of shigellosis were documented in 2005, representing a rate of 3.5 cases per 100,000 population.9 The CDC estimates that there are actually approximately 448,000 cases each year.10

Shigella sonnei is responsible for approximately 75% of the infections occurring in this country; Shigella flexneri causes most of the remaining cases, with Shigella boydii and Shigella dysenteriae responsible for less than 2% of cases.9

Shigella infections are common in confined populations, such as those in mental or penal institutions, in nursing homes or day care centers, or on Native American Indian reservations. Children younger than 5 years of age account for 30% of cases. An increased incidence has been documented among men who have sex with men and in the AIDS population.11 Spread is by the fecal-oral route, and humans are the only natural hosts. Shigellae can be found in large numbers around the base of toilets used by infected persons, and the organism readily passes through toilet tissue onto the fingers. Shigellae can be recovered in cultures of samples taken as long as 3 hours after contamination. In the last few years, a number of large outbreaks have been associated with recreational water venues such as swimming pools, water parks, fountains, hot tubs, and spas.10

Pathophysiology. Unlike Salmonella, which requires a very large inoculum to produce disease, as few as 50 to 100 Shigella bacilli can cause infection. No other enteric pathogen is so efficient in producing overt disease in humans. Infection generally is superficial, localized to the epithelial lining of the colonic mucosa; therefore, bowel perforation or invasion into the bloodstream is extremely rare. Bleeding occurs from superficial ulcerations of the mucosa.

Clinical presentation varies among Shigella species. S. sonnei typically causes high-volume, watery diarrhea with relatively few systemic signs. Infection with S. flexneri, S. dysenteriae, or S. boydii typically causes low-volume bloody diarrhea and more severe systemic symptoms.7

Clinical Presentation. The usual incubation period is 24 to 48 hours, and the clinical manifestations vary considerably, often appearing in a bimodal fashion. Mild, watery diarrhea with few if any constitutional symptoms or asymptomatic infection occurs in a significant proportion of infected persons. It is estimated that fever occurs in 58 to 100%, abdominal pain in 75 to 100%, tenesmus in 55 to 96%, bloody stool in 46 to 73%, and nausea or vomiting in 63 to 100%.5

When true dysentery develops, it ordinarily is preceded by a recognizable period of watery diarrhea lasting a few hours to a few days. Patients with dysentery have grossly bloody diarrhea, tenesmus, and significant constitutional symptoms and signs, such as fever, nausea, vomiting, headache, and myalgias. If symptoms are severe enough, profound dehydration and even circulatory collapse can occur. Children younger than 2 years of age may have associated neurologic manifestations, most commonly seizures, although lethargy or frank coma develops in a small percentage of patients. S. dysenteriae type 1 infection, rarely diagnosed in developed countries, is associated with the hemolytic uremic syndrome.

Generally, shigellosis is a self-limited disease. Patients become afebrile in 3 to 4 days, and the abdominal cramping and diarrhea resolve within 1 week. A significant number of untreated patients will continue to shed organisms in the stool for 2 or more weeks, and approximately 10% of patients will have a relapse unless the infection is treated with antibiotics.

Diagnostic Strategies. As with other invasive pathogens, most cases of shigellosis remain undiagnosed. Patients with mild, watery diarrhea and few if any constitutional symptoms can be sent home with conservative management and no investigative procedures. However, shigellosis should be considered in every patient with an acute febrile illness associated with diarrhea, especially those patients who appear ill or who have dysenteric stools.

Fecal white blood cells are present, usually in large numbers, in 85 to 95% of the cases, regardless of the gross appearance of the stool.3 Thus, finding leukocytes in watery stools can help identify shigellosis even in the absence of classic dysenteric stools. Occult blood is present in the stools of infected patients. Blood leukocytosis is common, and a significant leftward shift in the differential count is almost always seen. Results of blood cultures for Shigella are rarely positive. Sigmodoscopic examination reveals diffuse mucosal inflammation, often with multiple ulcerations.

A definitive diagnosis of shigellosis is made with stool culture. Stool culture results are positive in more than 90% of cases when samples are obtained during the first 3 days of illness; however, results are positive in only approximately 75% if samples are obtained more than 1 week after the onset of diarrhea.12

Differential Considerations. Considerations in the differential diagnosis include salmonellosis, Campylobacter enteritis, yersiniosis, E. coli O157:H7 infection, amebic dysentery, and ulcerative colitis.

Management. Treatment primarily involves the correction of fluid and electrolyte abnormalities. If S. sonnei or S. flexneri is cultured from the stool, the decision to administer antibiotics is based on the patient’s clinical condition and the feasibility of sanitary control. Asymptomatic or recovering patients do not need to be treated with antibiotics unless treatment is necessary for public health measures. Patients whose condition is not improving and those who are immunocompromised should be treated. Antibiotics shorten the clinical course and eradicate the pathogen from the stool, often within 48 hours.12 Whenever S. dysenteriae is isolated, the patient should be treated to prevent outbreaks of dysentery, even if the patient is asymptomatic when the culture result returns from the lab.

In the United States, more than 80% of Shigella organisms are resistant to ampicillin, and 47% are resistant to TMP-SMX.7 Significant resistance has not yet been found to the quinolone agents ciprofloxacin and norfloxacin, and one of these should be considered the drug of choice unless sensitivity studies demonstrate that the organism is sensitive to either ampicillin or TMP-SMX. Treatment is required for only 3 days in immunocompetent patients but should be extended to 7 to 10 days in the immunocompromised.7

Antimotility agents may prolong the fever, diarrhea, and excretion of Shigella in the stools and are contraindicated in patients with invasive shigellosis. However, they may be safe when used simultaneously with antibiotics. Follow-up stool cultures should be done in patients treated for S. dysenteriae infection to ensure eradication of the organism. Follow-up cultures, however, are not necessary after treatment for S. sonnei or S. flexneri infection, provided that the patient’s condition improves clinically. Shigellosis is a nationally notifiable disease.

Yersinia enterocolitica Gastroenteritis

Epidemiology. Yersinia enterocolitica, a gram-negative facultatively anaerobic bacterium, is a member of the family Enterobacteriaceae. Y. enterocolitica is a relatively infrequent cause of enteritis in the United States, with FoodNet surveillance systems
documenting approximately 1 case of culture-verified yersiniosis per 100,000 population.13 Y. enterocolitica infections are much more common throughout Scandinavia and Europe. In 2004, the incidence of human yersiniosis was 13.1 per 100,000 in Finland and 7.5 per 100,000 in Germany.14 Yersiniosis is more prevalent in children and more common in the winter months.

Pathophysiology. After oral ingestion, the bacterium invades the intestinal epithelium and localizes to lymphoid tissue of the intestinal mucosa, particularly Peyer’s patches. It then invades the regional mesenteric lymph nodes. Invasive enteritis is the clinical presentation in approximately two thirds of patients. Pseudoappendicitis and mesenteric adenitis account for the remainder of presentations. Infection originates from contaminated food or drink. The consumption of contaminated milk or contaminated raw pork has accounted for sporadic cases and several large outbreaks. Fecal-oral transmission to humans from a variety of animals, particularly cats, dogs, pigs, and direct person-to-person spread probably occur, but communicability appears to be low.13

Clinical Presentation. The clinical picture with Yersinia enterocolitica often resembles that with infection by other invasive intestinal organisms: fever (68%); colicky abdominal pain (65%); watery, greenish, and sometimes bloody (26%) diarrhea; and constitutional symptoms of anorexia, vomiting (39%), and malaise.3 However, in cases of Y. enterocolitica gastroenteritis, the abdominal pain and diarrhea usually persist for 10 to 14 days or longer.

In a substantial number of patients with yersiniosis, particularly adolescents and young adults, an ileocecalitis may develop. In these cases, lower abdominal pain with little or no diarrhea is the predominant symptom, and the clinical presentation may perfectly mimic that in acute appendicitis. Large outbreaks have been traced to contaminated milk, largely because in the relevant series, physicians noticed an extraordinary rise in the number of negative appendectomies.15

Postinfection manifestations, such as erythema nodosum or a persistent polyarthritis, occur in as many as 2 to 5% of patients, mainly adults. Other presentations include sacroiliitis, ankyllosing spondylitis, Reiter’s syndrome, exudative pharyngitis, pneumonia, empyema, and lung abscess. Y. enterocolitica septicemia is rare but is known to occur, most often in patients with diabetes mellitus, severe anemia, hemochromatosis, cirrhosis, or malignancy.13

Diagnostic Strategies. Approximately 70% of patients with Y. enterocolitica infection will present with signs and symptoms of invasive enteritis. The diagnosis of yersiniosis cannot be made on the basis of clinical presentation alone. A positive stool culture is required. Methylene blue staining of stool for fecal leukocytes yields a positive result in approximately 48% of cases of yersiniosis.1 Most laboratories do not routinely include Y. enterocolitica culture in the standard stool culture; Yersinia culture can be done by special request if clinically indicated (e.g., by history of Yersinia exposure, prolonged invasive enteritis despite a negative result on standard stool culture, or right lower quadrant pain with a normal appendix on imaging studies).

Stool cultures require special techniques and a long time for growth. Patients with Yersinia enterocolitis often continue to shed organisms in the stools well into convalescence, long after the diarrhea subsides. The mean duration of fecal shedding is approximately 6 weeks.

Differential Considerations. The diagnosis should be suspected in a patient with prolonged abdominal pain and diarrhea after what appears to be a common, usually self-limited gastroenteritis syndrome, or in a patient with symptoms similar to those of appendicitis or mesenteric adenitis. Y. enterocolitica infection also should be considered in the differential diagnosis of regional enteritis, which can closely mimic.

Management. Generally, Y. enterocolitica infection is self-limited at the diarrheal stage and resolves without treatment. As with other invasive gastrointestinal pathogens, antiperistaltic drugs are not recommended unless the patient is simultaneously treated with antibiotics.

Treatment with antibiotics has not been proved to be essential or efficacious in the management of uncomplicated Yersinia enterocolitis or in the pseudoappendicitis syndrome. However, because Yersinia organisms take a long time to grow on culture, in most studies the duration of illness before antibiotics were started was 1 to 2 weeks. Yersinia organisms usually are susceptible to TMP-SMX, which is the agent of choice when antibiotic therapy is indicated.3 Drug treatment does decrease the fecal shedding of the organism. Doxycycline in combination with an aminoglycoside is an alternative regimen, as is single-agent therapy with a quinolone.3 In immunocompetent adults, a 3-day course is sufficient; the course is extended to 7 to 10 days if the patient is immunocompromised. Treatment should be considered in patients who are still significantly ill at the time culture results return, particularly if the patients are immunocompromised or have a significant underlyng medical illness, or in cases in which the fecal shedding could represent a public health hazard. In those patients who interact with potentially susceptible persons, appropriate steps should be taken to ensure that they do not spread their infection.

Vibrio parahaemolyticus Gastroenteritis

Epidemiology. Vibrio parahaemolyticus is a halophilic (salt-requiring) gram-negative bacillus found naturally in warm marine environments such as the coastal seawaters of Japan, the United States, and other temperate-zone nations. In Japan, V. parahaemolyticus is the most common cause of bacterial enteritis, being responsible for approximately 70% of cases. The typical source is raw fish. In the United States, V. parahaemolyticus disease is much less common, with approximately 190 documented cases annually, or 0.25 per 100,000 population. The CDC estimates that approximately 3000 cases, 40 hospitalizations, and 7 deaths occur each year. U.S. cases typically are related to consumption of raw or undercooked shellfish, especially oysters (49%), although clams (38%), shrimp, lobsters, mussels, cockles, crabs, and scallops all have been implicated. Many cases occur as outbreaks on cruise ships or in persons who have patronized a common restaurant or seafood market. V. parahaemolyticus enteritis is much more common in the summer months, with 70% of cases occurring between the months of May and October, when warm seawater temperatures favor replication of the organism.16 At such times, 100% of oysters in local beds have been shown to harbor the organism. Attack rates from a common-source exposure are fairly high, but little evidence is available for human-to-human spread among family members of infected patients.17

Pathophysiology. The mechanism by which V. parahaemolyticus causes human enteritis is poorly understood, but seems to be related to production of a thermostable direct hemolysin (TDH) enterotoxin. Serotypes that produce TDH attach to the colonic epithelium and induce a secretory diarrhea as well as local hemolysis. An infectious dose of V. parahaemolyticus is thought to be 100,000 colony-forming units (CFU) or more, and the sale of oysters with 10,000 CFU or less per gram of oyster product is allowed in the United States. Still, transmission has occurred from oyster beds in which the colony count was less than 200 CFU per gram of oyster meat.17
Although enteritis is the most common clinical presentation, accounting for 60 to 80% of cases, *V. parahaemolyticus* infections also manifest as wound infections (34%) and septicemia (5%). Serious wound infections and septicemia occur primarily in persons with underlying liver disease, alcoholism, or diabetes mellitus.¹⁵

**Clinical Presentation.** Signs and symptoms usually appear 8 to 12 hours after the ingestion of contaminated food, but the incubation period can range from 4 to 48 hours. The predominant manifestation is acute diarrhea, but the volume of fluid lost generally is not large. Moderately severe abdominal cramps occur in 88%, nausea in 52%, vomiting in 39%, and fever in 33%. Vomiting generally is not prominent. The illness is almost invariably self-limited and seldom lasts longer than 24 to 48 hours.²²

*V. parahaemolyticus* infection should be suspected when a common-source outbreak of acute diarrheal disease occurs in persons exposed to fresh or frozen seafood. It also should be considered when fecal white blood cells are present in cases of acute invasive diarrhea linked to food poisoning.

**Diagnosis.** As with other types of acute invasive enteritis, the diagnosis of *V. parahaemolyticus* cannot be made on the basis of clinical presentation alone. The diagnosis is made by stool culture. Although blood agar and other nonselective media support the growth of this vibrio, isolation from the stool usually requires the use of a selective medium containing thiosulfate, citrate, bile salts, and sucrose (TCBS agar). This selective culture procedure is not part of the standard stool culture in most U.S. hospitals but can be obtained by special request in cases of outbreaks related to consumption of raw or undercooked shellfish, especially in coastal areas of the United States.¹⁶

**Management.** Because the disease is self-limited, most patients require no therapy. Although data on efficacy of antibiotic therapy are lacking, patients who still have diarrhea when culture results become available may benefit from treatment with tetracycline or fluoroquinolones or another antibiotic as guided by susceptibility testing.¹⁵ An occasional patient may require fluid replacement. Antimotility agents are not indicated.

Because *V. parahaemolyticus* is widely present in coastal waters, the only effective preventive measures are adequate cooking, refrigeration, and hygienic practice in the preparation of seafood for human consumption.

### Enterohemorrhagic (Shiga Toxin–Producing)

**Escherichia coli Gastroenteritis**

**Epidemiology.** Enterohemorrhagic *E. coli* was first recognized as a human pathogen in 1982 after two outbreaks of hemorrhagic colitis were traced to undercooked ground beef contaminated with *E. coli* serotype O157:H7 and distributed at a fast food restaurant chain. It is now recognized that *E. coli* O157:H7 is 1 of more than 30 serotypes of *E. coli* known to produce *Shigella*-like toxins and that these “Shiga toxin–producing *E. coli*” (STEC) as a group constitute a major cause of hemorrhagic colitis, hemolytic uremic syndrome, and thrombotic thrombocytopenic purpura in humans.¹⁵ The CDC estimates 110,000 cases and 2,100 hospitalizations per year in the United States and reports a 42% decrease in the incidence from 1996 to 2004, probably owing to improvements in food safety protocols.¹⁶ STEC infections have been documented in more than 30 countries on 6 continents.

Inadequately cooked hamburger has caused many large outbreaks.¹⁵ STEC, present in the intestines of healthy cattle, contaminates the meat during slaughter, and the grinding process then transfers the organisms from the surface of the meat to the interior. U.S. Department of Agriculture food safety regulations now require that hamburger be cooked thoroughly, to the point that the juices are no longer pink, to effectively kill *E. coli* organisms. Outbreaks also have occurred from consumption of venison, salami, pepperoni, cheese curds, apple cider, raw milk, and fruits and vegetables; from contamination of municipal water supplies; from animal contact in petting zoos; and from person-to-person spread in day care centers.² Food handlers with STEC-related diarrhea have contaminated meals responsible for institutional outbreaks. Enterohemorrhagic *E. coli* enteritis is more common in the summer months.

**Pathophysiology.** *Escherichia coli* O157:H7 is 1 of more than 30 serotypes of *E. coli* known to produce *Shigella*-like toxins, which are cytotoxic to the intestinal vascular endothelial cells and cause hemorrhagic colitis. STEC does not cause an invasive infection, but the clinical presentation is quite similar to that with an invasive bacterial infection. Bacteria attach to the surface epithelium of the cecum and colon and elaborate verotoxin. Clinical signs and symptoms correlate with presence of free verotoxin in the colon. Histologic changes include apoptosis in the surface epithelium, mucus depletion, and neutrophilic infiltration of the lamina propria and epithelium. The verotoxin-induced syndrome of pain and (often) bloody diarrhea closely mimics that caused by other invasive pathogens.

It appears that STEC serotypes are associated with two different *Shiga*-type toxins. The development of hemolytic uremic syndrome is associated primarily with serotypes that produce Shiga toxin 2. The CDC estimates that greater than 90% of cases of hemolytic uremic syndrome are associated with the serotype *E. coli* O157:H7.¹⁹

**Clinical Presentation.** After an incubation period of 3 to 4 days, patients initially produce watery diarrhea that becomes bloody hours to days later. Approximately 80 to 90% of patients report bloody stools.³ The amount of blood varies, but stools passed may appear to consist wholly of blood, and the infection may masquerade as gastrointestinal bleeding from noninfectious causes. The bloody diarrhea typically is accompanied by severe abdominal cramps, pain, and often vomiting. Fever is a feature in fewer than one third of cases and, if present, usually is low grade.³ This helps differentiate STEC infection from that due to other invasive organisms. Fecal leukocytes are found in approximately 50% of cases, but in small numbers, in contrast with the sheets of white blood cells seen in *Shigella* dysentery.³ Endoscopic, histologic, and radiographic studies demonstrate only nonspecific changes consistent with an inflammatory hemorrhagic colitis and do not accurately distinguish STEC infection from other causes of colitis.²⁰

Uncomplicated infection resolves spontaneously over 7 to 10 days. A carrier state may last another 1 to 2 weeks, but it also resolves spontaneously. Chronic diarrhea has very rarely been described.²¹

**Complications.** *E. coli* O157:H7 hemolytic colitis has been associated with two serious complications: hemolytic uremic syndrome and thrombotic thrombocytopenic purpura. These clinically similar disorders share the following features: microangiopathic hemolytic anemia, thrombocytopenia, fever, neurologic deficits, and renal dysfunction. In thrombotic thrombocytopenic purpura, neurologic findings predominate, and renal dysfunction is unusual. The opposite is seen with hemolytic uremic syndrome, which is more common in children, especially those younger than 4 years, occurring in approximately 8% of cases.²¹ Of these, 3 to 5% are fatal.²¹ Approximately 22 to 40% of elderly persons in nursing home outbreaks acquire hemolytic uremic syndrome, and 50 to 80% of these patients die. Thrombotic thrombocytopenic purpura...
is seen in 2 to 3% of cases, most often in immunosuppressed patients. Hemolytic uremic syndrome and thrombotic thrombocytopenic purpura typically appear 5 to 20 days after the onset of infection, and the diarrhea can be totally resolved and forgotten by the time a diagnosis is established. Death from \( E. \ coi \) O157:H7 hemorrhagic colitis alone or from one of the complications occurs primarily among the elderly.\(^{15} \)

**Diagnostic Strategies.** The CDC recommends that all patients who present with bloody diarrhea be tested for STEC infection and that \( E. \ coi \) O157:H7 be included in the standard stool culture in all clinical laboratories. Diagnosis requires specific stool culture techniques. In addition to the routine battery of media, specimens should be plated onto sorbitol-MacConkey (SMAC) medium. The O157:H7 strains of \( E. \ coi \) are sorbitol-negative at 18 to 24 hours of growth on this medium and can be rapidly identified using various serologic tests, such as latex agglutination or fluorescent antibody testing. A commercial Shiga toxin enzyme immunoassay (EIA) was introduced in 1995 in order to assist clinical laboratories in identifying non-O157 Shiga toxin–producing strains of \( E. \ coi \). The CDC now recommends that all stools submitted for culture also be tested for STEC-associated verotoxin using EIA, and that non-O157 STEC be sent to the CDC for typing. As of 2007, only 9% of clinical laboratories in the United States test for STEC using EIA technology.\(^{19} \)

**Differential Considerations.** Hemorrhagic \( E. \ coi \) infections may be misdiagnosed as ischemic colitis, inflammatory bowel disease, intussusception, or another infectious colitis. The examining physician should test for STEC when considering a diagnosis of one of these entities.

**Management.** Antibiotic therapy does not shorten the clinical course or eradicate the organism. Moreover, treatment with antibiotics to which the organism is resistant may increase the risk for hemolytic uremic syndrome by eliminating competing bowel flora. However, the degree to which antibiotic treatment truly increases the risk for hemolytic uremic syndrome remains controversial.\(^{17,18} \)

Retrospective studies in adults suggest an association between antibiotic use and the development of hemolytic uremic syndrome but may have been biased due to preferential use of antibiotics in the more serious cases. Because antibiotic treatment is of no clinical benefit and may increase the risk of hemolytic uremic syndrome, it is not recommended for patients with known infection with \( E. \ coi \) O157:H7.

Empirical antibiotic treatment for bloody diarrhea should be approached with caution. Empirical treatment is not recommended in children because of the increased incidence of hemolytic syndrome. In adults, empirical treatment is recommended only for those with a temperature above 38.5°C, since the presence of significant fever suggests a pathogen other than \( E. \ coi \) O157:H7.

### Aeromonas Gastroenteritis

**Epidemiology.** \( \text{Aeromonas} \) organisms are gram-negative, facultatively anaerobic, rod-shaped bacteria of the family Vibrionaceae. \( \text{Aeromonas} \) species are ubiquitous worldwide in fresh and brackish water and also contaminate the food and water supply.\(^{19,22} \) \( \text{Aeromonas} \) organisms grow at a range of temperatures but are isolated with increased frequency in summer months. No figures are available on the incidence of \( \text{Aeromonas} \) gastroenteritis in the United States. An association with human enteritis is difficult to confirm because no major outbreaks have been linked to \( \text{Aeromonas} \) species and the organism often is found in the feces of asymptomatic persons. Still, several small outbreaks have been documented in travelers and by case-control studies; it is likely that certain serotypes do cause gastroenteritis in humans.\(^{23,24} \)

Drinking untreated water, usually from private wells or springs, causes most cases of diarrhea from \( \text{Aeromonas} \) bacteria.\(^{22} \) \( \text{Aeromonas} \) infection has not been associated with consumption of shellfish. \( \text{Aeromonas hydrophila} \) causes wound infection; septicemia occurs in persons of advanced age or with underlying gastrointestinal disease such as colon cancer, cirrhosis, or hepatobiliary or inflammatory bowel disease or history of recent hospitalization or antibiotic treatment. In some published series, \( \text{Aeromonas} \) infection causes 2 to 10% of all cases of diarrhea in children.\(^{22,23} \)

**Pathophysiology.** The exact mechanism by which \( \text{Aeromonas} \) species produce diarrhea has not yet been explained. Both enterotoxins and cytotoxic toxins may be produced, and the organisms may have some invasive characteristics.

**Clinical Presentation.**

Typical signs and symptoms are watery diarrhea, abdominal cramps (50%), vomiting (25%), and fever in approximately one half of the patients.\(^{24} \) Children tend to have a more acute, severe illness than that typical for adults. In untreated patients, diarrhea persists for 2 to 10 weeks, with more prolonged illness in adults than in children. Generally, leukocytes and occult blood are absent from the stool; however, patients can have a severe colitis, including fever, fecal leukocytes, and bloody diarrhea, which can mimic Crohn’s disease or ulcerative colitis. Stool should be examined for the presence of \( \text{Aeromonas} \) infection before establishing a diagnosis of inflammatory bowel disease.

**Diagnostic Strategies.** Diagnosis is made by stool culture, but culture for \( \text{Aeromonas} \) species is not part of the standard stool culture, and the clinician must request that the laboratory culture specifically for this organism. \( \text{Aeromonas} \) infection should be suspected in children or immunocompromised patients with diarrhea associated with a history of drinking from untreated water sources.

**Management.** No controlled trials have been conducted that clearly demonstrate a benefit to antibiotic therapy. In most patients, \( \text{Aeromonas} \) enteritis is mild and self-limited, and antibiotic therapy probably is not warranted. In the case of severe disease, prolonged diarrhea, or an immunocompromised host, double-strength TMP-SMX is the drug of choice, but the quinolones also are effective.\(^{3} \) A 3-day course is recommended.

### Plesiomonas shigelloides Gastroenteritis

**Epidemiology.** \( \text{Plesiomonas shigelloides} \) is a gram-negative, facultatively anaerobic bacterium of the family Vibrionaceae. The organism is found in a variety of settings, including animals, soil, and in freshwater and dilute saltwater bodies including the Gulf of Mexico. Humans usually are infected by contaminated food or water or after contact with colonized animals. Worldwide, \( P. \ shigelloides \) enteritis is well documented in the tropical and subtropical areas of Africa, Asia, and Australia. In the United States and Europe, most cases occur after travel to tropical areas or after consumption of raw shellfish, especially oysters.\(^{15} \) Sporadic diarrheal illness occurs in both normal and immunocompromised hosts. Large outbreaks have occurred, usually resulting from oyster consumption.\(^{15} \)

**Pathophysiology.** Evidence supporting a pathogenic role for \( P. \ shigelloides \) includes documented outbreaks associated with contaminated shellfish, a very low asymptomatic carrier rate, and recovery from diarrheal illness after antibiotic therapy. The mechanism of disease production remains poorly under-
The incubation period is only 1 to 2 days in duration. Abdominal pain is noted in 72% of patients. Diarrhea is watery in 73% of patients and grossly bloody in 24%. Occult blood is noted in 44%, emesis in 38%, and fever in 51%. Symptoms resolve after 1 to 3 days in most cases but occasionally may persist for up to 8 weeks. The duration of illness usually is shorter in children.

Diagnosis of *P. shigelloides* infection should be considered in patients with a typical invasive-appearing diarrhea, especially if the stools are bloody or when the onset of illness occurs shortly after the ingestion of raw shellfish or foreign travel, particularly to Mexico. *P. shigelloides* is increasingly recognized as a pathogen in immunocompromised patients.

**Diagnostic Strategies.** Definitive diagnosis is obtained by stool culture. The laboratory must be notified when this organism is considered. Unless oxidase testing is done, *Plesiomonas* may be indistinguishable from Enterobacteriaceae on nonselective culture media. Patients with *Plesiomonas* infections should be evaluated for possible immunodeficiency.

**Management.** Antibiotic therapy usually is not necessary for *P. shigelloides* enteritis because of the brief duration of illness. In patients who are immunocompromised and those with severe or prolonged symptoms, antibiotic treatment may be of benefit. *P. shigelloides* usually is resistant to ampicillin but susceptible to TMP-SMX, the quinolones, cephalexin, gentamicin, and chloramphenicol. The current recommended treatment regimen is TMP-SMX, 160 mg/800 mg twice daily for 3 days; ciprofloxacin, 500 mg twice daily; or norfloxacin, 400 mg twice daily for 3 days. Follow-up evaluation is not necessary unless the patient is immunodeficient or does not respond clinically.

**Bacillus anthracis** Infection

**Epidemiology.** Although gastrointestinal anthrax is rare in developed countries, large outbreaks still occur in agricultural regions throughout the world. Anthrax also has been used as a weapon of bioterrorism in regions not normally susceptible to the disease. As early as the 1930s, groups experimented with anthrax-impregnated chocolate as a weapon against their enemies. Awareness of the spectrum of clinical presentations of gastrointestinal anthrax is important not only for the welfare of the patient but for prompt recognition of potential terrorist activity.

Traditionally, gastrointestinal infection has been estimated at less than 1% of all human anthrax cases. It was thought that 95% of cases involved cutaneous symptoms and 5% were limited to the respiratory tract. However, because gastrointestinal anthrax can cause only mild and self-limited symptoms, many persons with the gastrointestinal form may not seek medical treatment. Studies of several large outbreaks in Uganda and Thailand suggest that the gastrointestinal form is observed in 74 to 92% of patients who contract anthrax after eating the meat of infected herbivores.

Areas endemic for anthrax exist in all continents containing tropical and subtropical regions. Thailand, India, Iran, Gambia, and Uganda all have reported deaths from gastrointestinal anthrax. Within the United States, naturally occurring anthrax exposure has been documented in several areas, including Minnesota. Although no predilection for time of year in endemic areas has been documented, the disease is more common in animals after substantial rainfall following a period of drought, a pattern known as “anthrax weather.”

In the United States, gastrointestinal anthrax has not been reported, although cutaneous anthrax is reported once or twice each year. Populations at risk for naturally occurring anthrax are persons living in rural, agricultural areas who have ingested undercooked meat contaminated with anthrax spores. As with many other organisms, the pediatric population seems to be most at risk for serious or fatal illness.

**Pathophysiology.** *Bacillus anthracis* is a nonmotile, rodlike, gram-positive aerobic bacillus that produces central oval-shaped spores. It is introduced into the food chain most often after ingestion by herbivores such as cattle. The animal usually becomes visibly ill, and the meat often is identifiable as abnormal after slaughter, thereby preventing human exposure. Even when the meat reaches a consumer, adequate cooking usually reduces the inoculum to harmless levels. However, if the meat is undercooked, a high rate of infectivity results. Intentional placement of anthrax spores in the food or water supply could theoretically cause outbreaks of gastrointestinal anthrax, although this has not been reported.

When swallowed, anthrax spores stick to the gastrointestinal epithelium, where they germinate and create multiple superficial ulcerations. Lesions have been identified from the oral cavity to the cecum. The vegetative cells may at times migrate into the bloodstream, where they rapidly multiply and can cause septicemia. *Bacillus anthracis* protects itself with an antiphagocytic capsule and produces two exotoxins, lethal and edema toxins.

**Clinical Presentation.** A minority of patients who ingest anthrax spores remain asymptomatic, and in endemic areas, adults often are thought to have some natural immunity acquired through previous exposure. Of those in whom symptoms do develop, presentation can vary widely, ranging from mild watery diarrhea to fulminant upper and lower gastrointestinal bleeding, septicemia, and death. The incubation period for gastrointestinal symptoms ranges from 1 to 6 days, with larger inocula and more severe disease developing earlier. For disease confined to the oropharynx, patients usually present with complaints of sore throat, fever, dysphagia, hoarseness, and painful neck swelling. The swelling results from marked lymphadenopathy and tissue edema and can become severe enough to compromise breathing.

Much information concerning intestinal anthrax has been derived from two large outbreaks in Uganda and Thailand, respectively. A majority of the patients presented with isolated diarrhea. Nausea, vomiting, and severe abdominal pain with distention also developed in a minority of the patients. Most patients were febrile, with temperatures above 39°C, and blood in both the vomitus and diarrheal stool was common.

With this form of anthrax, lesions throughout the gastrointestinal tract are often surrounded by significant edema and can lead to obstruction, necrosis, and perforation. Intra-abdominal lymphadenopathy and splenomegaly develop as well. The lymphatic tissue often becomes hemorrhagic, and ascites may form, with fluid shifts large enough to cause shock and even death.

In cases of primary gastrointestinal anthrax, the superficial mucosa is always involved, with ulcerations visible on endoscopic examination. These findings are in contrast with those with disseminated infection from pulmonary anthrax, in which the lesions begin submucosally as a result of seeding from the bloodstream. These lesions can then secondarily ulcerate to the surface of the gastrointestinal tract epithelium. Untreated, gastrointestinal anthrax may last weeks and can be, but is not always, fatal.

**Diagnostic Strategies.** Diagnosis of *B. anthracis* in cases of oropharyngeal disease is best accomplished by swabbing the oral...

COMMENTS/UNTREATED
High attack rates, gastrointestinal and
peritonitis.
In patients with severe disease manifested as marked ascites and abdominal pain, the clinical presentation may be similar to that in patients with end-stage liver disease with peritonitis.
Management. Traditionally, penicillin has been used to treat gastrointestinal anthrax. Cases of penicillin resistance have been documented, however, and a logical assumption is that a resistant strain would be chosen for use as a weapon of bioterrorism. Therefore, current recommendations from the CDC are to treat gastrointestinal cases in the same manner as for terrorism. Therefore, current recommendations from the CDC.

Differential Considerations. Oropharyngeal anthrax lesions are sometimes confused with peritonsillar abscess, although cervical swelling is unusually severe in cases of oropharyngeal anthrax. The marked swelling of the oral lesions is secondary to edema and should not yield pus if incision and drainage are performed. Gastrointestinal anthrax can cause enough upper gastrointestinal bleeding to be confused with variceal rupture. In patients with severe disease manifested as marked ascites and abdominal pain, the clinical presentation may be similar to that in patients with end-stage liver disease with peritonitis.

Pathogens associated with toxin-induced bacterial enteritis are summarized in Table 92-3. In general, gastroenteritis due to toxin-forming bacteria and viral agents will manifest as an acute noninvasive enteritis, with watery diarrhea, minimal fever, little or no abdominal cramping, and absence of fecal leukocytes and erythrocytes. Treatment is primarily supportive, and diagnostic testing generally is not indicated in otherwise healthy patients. A specific diagnosis may be of help in attempting to identify a common source during large outbreaks.

Staphylococcal Food Poisoning

Epidemiology. Staphylococcus-related food poisoning occurs after multiplication of an enterotoxin-forming strain of Staphylococcus that is present in the food before its ingestion. Food contamination with Staphylococcus is extremely common because the organism is ubiquitous in the environment. It can be isolated from the hands of approximately 50% of persons in the general population. Most protein-rich foods support the growth of staphylococci, especially ham, eggs (even hard-boiled), custard-filled pastries, mayonnaise, and potato salad.

Temperatures between 45° and 140° F for only a few hours will allow proliferation of the organism in contaminated food and production of sufficient enterotoxin to cause disease. Foods

</tbody>
</table>
containing sufficient enterotoxin to produce violent illness usually are normal in appearance, odor, and taste. Large outbreaks are common worldwide, particularly in institutions such as school or hospital cafeterias, military bases, airlines, and restaurants.

Pathophysiology. Although the bacterium itself is killed by cooking at temperatures above 140°F, *Staphylococcus* enterotoxin is heat-stable. Thus, once it is present in food, reheating or even boiling will not prevent illness. The toxin has no local effect on the digestive tract. It is a potent stimulator of T lymphocytes in the host, stimulating their proliferation and the release of various cytokines. The gastrointestinal effects are believed to be mediated by the release of histamine and leukotrienes from mast cells.  

Clinical Presentation. The illness has an explosive onset, beginning 1 to 6 hours after ingestion of the contaminated food. Cramping and abdominal pain, with violent and often-repeated retching and vomiting, are the predominant symptoms. Diarrhea is usually mild; occasionally it is absent entirely, and infrequently profuse. Fever occasionally is present. Staphylococcal food poisoning is short-lived, usually subsiding in 6 to 8 hours and rarely lasting as long as 24 hours. Patients often are recovering by the time they seek medical attention. Attack rates are very high, often greater than 75% of the population at risk. The short incubation period and multiple cases among persons eating the same meal are highly suggestive of this disease. Examination of the stool is noncontributory, and no practical laboratory test is clinically available to confirm the diagnosis. The epidemiologic circumstances, however, usually provide adequate suggestive evidence.

Management. Rapid, uncomplicated, spontaneous recovery is the rule. Parenteral antiemetic agents help control vomiting. Intravenous fluids should be given to patients with significant dehydration and ongoing vomiting, particularly the very young, the elderly, and debilitated patients. Antibiotics are of no value because staphylococcal food poisoning is caused by preformed enterotoxin and not by viable microorganisms. Adherence to strict personal hygiene practices by food handlers and immediate refrigeration of foods not due for immediate consumption are the most important preventive measures. Ordinary refrigerator temperatures prevent production of the enterotoxin. Food should not be allowed to stand at room temperature for long periods before being served.

**Clostridium perfringens** Food Poisoning

Epidemiology. *Clostridium perfringens* food poisoning is one of the most commonly reported food-borne illnesses in the United States, with at least 10 to 20 outbreaks reported annually. Most cases occur in large groups, with dozens or even hundreds of persons affected. Illness is caused by the ingestion of meat or poultry heavily contaminated with *C. perfringens* type A heat-resistant spores. The organism also is ubiquitous in the environment and in human and animal feces. Typically, poisoning results from ingesting food that is cooked more than 24 hours before consumption, allowed to cool slowly at room temperature, and then served either cool or rewarmed. During this period of incubation, spores that survived cooking germinate, and clostridia multiply to reach sufficient numbers to constitute an infectious inoculum.

Pathophysiology. Ingestion of live organisms is required to produce disease, but illness is not caused by infection; rather, it is from an enterotoxin produced by sporulation of the organism in the gastrointestinal tract. The enterotoxin is responsible for all of the symptoms of *C. perfringens* food poisoning.

Clinical Presentation. Symptoms usually appear within 6 to 12 hours but can occur up to 24 hours after ingestion of the contaminated food. Frequent passage of watery diarrheal stools and moderately severe abdominal cramping are the major symptoms. Fever, nausea, and vomiting are rare. The illness is self-limited and rarely lasts for more than 24 hours.

*C. perfringens* food poisoning should be considered in a patient who experiences an acute onset of abdominal cramps and watery diarrhea shortly after eating a suspect meat or poultry dish and when others who ate the same meal are similarly ill. Leukocytes and erythrocytes are not present on stool examination.

Complications. A rare type of *Clostridium* food poisoning termed *enteritis necroticans* (also known as “pig-bel”) occurs after the ingestion of foods heavily contaminated with the type C strain of *C. perfringens*. The illness is characterized by an acute onset of severe abdominal pain, vomiting, diarrhea, prostration, and shock and may be rapidly fatal. Postmortem examination reveals a diffuse, hemorrhagic, necrotizing enteritis of the jejunum, ileum, and colon.

Management. Occasionally, a patient will need intravenous fluid replacement. Antibiotics are of no value because of the toxigenic nature and brief duration of the disease. Food poisoning from *C. perfringens* can be prevented by avoiding long periods of warming or cooling of foods that have already been cooked.

**Bacillus cereus** Food Poisoning

Epidemiology. *Bacillus cereus* is an aerobic, spore-forming, gram-positive rod that is a common cause of food-borne illness. The organism is one of the most frequently isolated soil bacteria. Because of its abundance and the hardiness of its spores, *B. cereus* contaminates nearly all agricultural products and plays a major role in the spoilage of food items, including pasteurized milk and milk products. It commonly is isolated from pasta, rice, dairy and dried milk products, spices, dried foods, meat, chicken, vegetables, seafood, fruits, and grains. Because it is ubiquitous and tolerates extremes of temperature, control of this bacterium in the food-processing environment is very difficult to achieve. It is estimated that *B. cereus* causes more than 27,000 cases of food poisoning in the United States each year.

*B. cereus* causes two distinct clinical syndromes: an emetic form produced by a heat-stable, *Staphylococcus*-like enterotoxin known as cereulide and a diarrheal form resulting from a heat-labile enterotoxin known as HBL, which is similar to that of *E. coli*. The emetic form usually is caused by the ingestion of contaminated fried rice, although beef, poultry, vanilla sauce, pasteurized cream, milk pudding, pasta, and infant formula also have been implicated. The diarrheal syndrome usually is associated with ingestion of HBL in meats or vegetables, but reported outbreaks also have involved fish, soups, sauces, and dairy products.

Pathophysiology. The heat-resistant spores of *B. cereus* survive boiling and then germinate when boiled foods such as fried rice are left unrefrigerated. The vegetative forms then multiply and produce toxin. Flash-frying or brief reheating of the food before serving often is not sufficient to destroy the preformed, heat-stable emetic toxin. Improper holding temperatures for cooked food is the most common feature of *B. cereus* food-borne illness.

Clinical Presentation. The emetic syndrome is clinically indistinguishable from that caused by staphylococcal enterotoxin. After an incubation period of 1 to 5 hours, profound vomiting and abdominal cramping occur in all patients. Diarrhea is present in approximately 25 to 30% of persons affected. The duration is short, usually less than 10 hours, and patients recover uneventfully.
The diarrheal syndrome begins after an incubation period of 6 to 14 hours and is characterized by diarrhea in all patients and by abdominal cramps in approximately 75%. Vomiting occurs in only 20% of cases. The duration of illness ranges from 12 to 36 hours. Symptoms are essentially the same as for food poisoning produced by *Clostridium perfringens*, although vomiting is less common with *C. perfringens*.

*Bacillus cereus* food poisoning should be suspected whenever an illness localized predominantly to the upper gastrointestinal tract develops less than 6 hours after eating, or whenever a predominantly lower intestinal tract illness occurs 6 to 24 hours after a suspect meal, usually of meats or vegetables.

**Diagnostic Strategies.** Because of the brief and noninvasive nature of the illness, diagnostic testing typically is not performed. In response to large outbreaks, public health authorities may elect to test common food sources. Isolation of 10⁵ colony forming units per gram from incriminated foods confirms the diagnosis. More recently, a real-time PCR assay has been developed that can detect the presence of *B. cereus* emetic toxin within 2 hours. This assay is not yet commercially available.³⁵

**Management.** Both syndromes generally are mild and self-limited. Antibiotics are not indicated because symptoms are mediated by enterotoxins. Parenteral antiemetic agents provide effective relief in patients presenting with violent vomiting. *B. cereus* food poisoning is preventable if boiled rice or cooked foods are promptly eaten or refrigerated and not left to sit at room temperature.

### Cholera and Gastroenteritis Due to Non-cholera Vibrios

**Epidemiology.** In addition to *V. parahaemolyticus*, other halophilic marine *Vibrio* species have increasingly been determined to be causes of acute gastroenteritis associated with seafood. Their epidemiology is identical to that of *V. parahaemolyticus*: ubiquitous presence in coastal seawater, outbreaks associated with the eating of raw or inadequately cooked shellfish, and an incidence markedly limited to the warmer months of the year.³⁵ Outbreaks of true cholera continue to occur sporadically along the Gulf Coast of the United States from inadequately cooked crabs or oysters. Other implicated foods include imported seafood, cooked rice, frozen or fresh coconut milk, and commercially prepared cut cantaloupe.³⁵ Cholera outbreaks in South America and India have led to an increasing number of cases of cholera imported into the United States. The CDC reports 0 to 5 cases annually.³⁶

**Pathophysiology.** The difference between these species and *V. parahaemolyticus* lies in the mechanism of pathogenesis. *V. parahaemolyticus* produces disease directly by an invasive intestinal infection, whereas these strains produce an enterotoxin in vivo that is responsible for the diarrhea. Therefore, symptoms resemble those of other forms of enterotoxin-induced gastroenteritis and not those caused by invasive pathogens. The enterotoxin of the non-cholera vibrios is antigenically similar to *V. cholerae* enterotoxin and produces a similar diarrheal illness, although it is much less severe.³⁵

**Clinical Presentation.** Patients with classic epidemic cholera experience copious “rice water” diarrhea, abdominal cramps, and often nausea and vomiting within 24 to 48 hours after ingesting contaminated seafood. A low-grade fever may be present. In these severe cases (cholera gravis), rates of diarrheal fluid loss can reach 1 L per hour. Nearly one half lose enough fluids to necessitate hospitalization, and fatality rates can reach 25 to 50% in untreated populations. The median duration of illness is approximately 7 days, quite unlike the 1- to 2-day course of *V. parahaemolyticus* infection.³⁵

Despite the notoriety of the classic form of cholera, the CDC estimates that only 1 in 20 cases are associated with cholera gravis. A majority of affected patients experience a relatively mild diarrheal illness that may go undocumented. Cholera is extremely rare in the United States, even among returning travelers, with a documented incidence of 1 case per 1 million population annually.³⁶

Another *Vibrio* species, *Vibrio vulnificus*, also is associated with eating raw seafood, especially raw oysters. *V. vulnificus* can cause self-limited gastroenteritis with onset approximately 16 hours after ingestion of contaminated food by healthy persons. In the compromised host, this organism causes serious wound infections after contact of seawater with open wounds, or a syndrome of primary septicemia characterized by hemorrhagic bullae of the skin and rapidly progressive septic shock. *V. vulnificus* infection is the leading cause of death in the United States associated with consumption of seafood. Septicemia carries a mortality rate of approximately 50% in patients with significant underlying disease, particularly chronic liver disease.³⁵ All patients with chronic liver disease, alcoholism, AIDS, other immunodeficiency states, and any significant chronic disease should be advised to avoid all raw shellfish.³⁷

**Diagnostic Strategies.** Because these are noninvasive vibrios, unlike *V. parahaemolyticus*, stained fecal smears will not show leukocytes or erythrocytes. Stool cultures will quickly identify the organisms if plated on appropriate TCBS medium.³⁵

**Management.** Patients with classic cholera often will lose enough fluids to require rehydration therapy. The World Health Organization oral rehydration formula has been used successfully to treat cholera worldwide.³⁷ The use of either oral or intravenous fluid hydration is dictated by the clinical picture. The role of antibiotics in the treatment of intestinal infections caused by noncholera vibrios is not clearly established. However, appropriate antibiotic regimens have been shown to decrease both the severity and the duration of cholera and may have the same effect on the diarrheal disease caused by these marine vibrios.³⁵ Choices include a single oral dose of either ciprofloxacin 1 g or doxycycline 300 mg; and a 3-day regimen of double-strength TMP-SMX twice a day.³⁵ Prevention, as with *V. parahaemolyticus* infection, depends on proper handling and avoidance of inadequately cooked seafood. Cholera is a nationally reportable infection.

A recently developed oral cholera vaccine is licensed and available in other countries. The oral vaccine appears to provide better immunity with fewer adverse effects than the previously available parenteral vaccine. The CDC does not recommend this vaccine for travelers, and it is not available in the United States.³⁵

### Scombroid Fish Poisoning

**Epidemiology.** Scombroid fish poisoning is a growing problem in the United States. The disease takes its name from the family Scombroideae (e.g., tuna, mackerel, skipjack, bonito, and related species) and results from the ingestion of a wide variety of dark-meat fish, including nonscombroid species such as herring, bluefish, anchovy, sardine, amberjack, black marlin, and mahi mahi. The fish species most commonly implicated are mahi mahi, tuna, and bluefish.³⁸ Restaurants serve these fish under various names such as mackerel, swordfish, bonito, dolphin, or amberjack, or they may make their appearance in the generic “tuna salad sandwich.”

Most U.S. cases occur in Hawaii and Florida, followed in frequency by California, New York, Washington, and Connecticut. However, scombroid poisoning can occur in any location where “fresh fish” are flown in on a regular basis.
Pathophysiology. Implicated species naturally contain unusually high levels of histidine. Scombroid fish poisoning results from the ingestion of heat-stable toxins produced by bacterial action on the histidine present in the dark meat of the fish. The responsible bacteria are normal constituents of the surface marine flora, rather than contaminants. The histidine decarboxylase activity of these organisms produces histamine and histamine-like substances, which cause the symptoms of scombroid fish poisoning. High levels of histamine in the fish correlate directly with the occurrence of the illness. Formation of the scombrotokins is directly related to improper preservation and refrigeration of the fish from the time they are caught until the time they are cooked. Generally, the problem is caused by improper refrigeration by the supplier, rather than being the fault of the restaurant serving the fish.

Clinical Presentation. The symptoms of scombroid fish poisoning resemble those of histamine intoxication. While eating the fish, the patient may note a metallic, bitter, or peppery taste, although many affected fish do not have an abnormal odor or taste. Symptoms usually develop abruptly within 20 to 30 minutes and consist of facial flushing, diarrhea, severe and throbbing headache, palpitations, and abdominal cramps. Other manifestations may include dizziness, dry mouth, nausea and vomiting, and urticaria. The facial flushing resembles a sunburn and can extend over the entire skin surface. The conjunctivae usually are injected. The duration of the major symptom complex generally is less than 6 hours, and although weakness and fatigue persist longer, the clinical course usually is benign. The attack rate is very high; most persons sharing the same toxic fish will become ill.

Management. Parenteral antihistamine therapy, such as diphenhydramine 50 mg IM or IV or cimetidine 300 mg IM or IV, usually promptly relieves all symptoms. Rarely, intravenous fluids are necessary. The disease is preventable if fish are properly handled, especially if they are refrigerated early and adequately. This is not an allergic reaction, so patients should not be told they are allergic to these fish, nor should they be prohibited from eating them again in the future.

Ciguatera Fish Poisoning

Epidemiology. Ciguatera fish poisoning is a common public health problem, with appreciable economic significance. It is endemic in tropical regions but is found worldwide. The CDC estimates that 50,000 to 100,000 people per year become ill from ciguatera poisoning. Fish caught around Hawaii and Florida cause most of the cases, but because the responsible ocean fish are now commonly transported inland, cases can be seen virtually anywhere in the country.

Ciguatoxin is produced by the marine dinoflagellate Gambierdiscus toxicus, which attaches itself to marine algae and is passed up the food chain. The lipid-soluble toxin accumulates in the tissues of the larger predacious coral reef fish, with the highest concentrations in the liver, intestines, head, and roe. It does not affect the fish in any way. Only humans suffer its ill effect when the toxin is ingested.

More than 400 fish species that frequent coral reefs have been implicated as ciguatoxin carriers, but fewer than 50 are commercially important. Those implicated in ciguatera poisoning include amberjack, barracuda, grouper, king mackerel, parrotfish, sea bass, snapper, sturgeon, surgeonfish, and ulua.

Pathophysiology. Ciguatera fish poisoning results from the ingestion of the ciguatoxin neurotoxin. Ciguatoxin is heat-and acid-stable, odorless, and tasteless. It is not deactivated by cooking or freezing, nor is it eliminated by drying, salting, smoking, marinating, or pickling. It is not possible to predict whether a fish contains sufficient amounts of the toxin to produce illness. Ciguatoxin has both anticholinesterase and cholinergic properties, but its neurotoxicity is mediated by its effect on sodium channels. Ciguatoxins cause a hyperpolarizing shift of the voltage dependence of channel activation such that sodium channels are open at resting membrane potential. Spontaneous firing of neurons occurs as tetrodotoxin-sensitive sodium channels are activated, giving rise to the typical neurolologic signs and symptoms.

Clinical Presentation. Ciguatera fish poisoning most commonly is seen in the spring and summer months. The incubation period is approximately 2 to 6 hours, but a delay of 12 to 24 hours is not unusual. Attack rates are very high; 80 to 90% of persons exposed become ill. Symptoms tend to be related to the amount of toxin ingested and vary considerably in their severity. If not fully recovered from an initial ingestion of ciguatoxin, affected persons are likely to have much more serious symptoms from a second ingestion.

Classically, patients exhibit both gastrointestinal and neurolologic symptoms. The gastrointestinal symptoms (e.g., nausea, vomiting, diffuse watery diarrhea, crampy abdominal pain, and diaphoresis) tend to appear first and resolve over the first 24 hours. The constellation of neurolologic symptoms consists largely of dysesthesias and paresthesias around the throat and the perioral area; “burning feet,” which may resemble alcoholic peripheral neuropathy; “loose, painful teeth”; and sometimes central nervous system changes, such as ataxia, weakness, vertigo, visual hallucinations, and even confusion and coma.

Distortion of temperature perception is vividly described by patients with ciguatera poisoning. Cold allodynia, defined as dysesthesia experienced on contact with cold water or cold objects, is almost pathognomonic of ciguatera poisoning and often is incorrectly referred to as “cold-hot temperature reversal.” Another classic feature is either a return or a worsening of all of the symptoms after ingestion of alcohol.

Ciguatera poisoning lasts an average of 1 to 2 weeks, but at least one half of its victims are still symptomatic at 8 weeks. The neurolologic symptoms, particularly the paresthesias and dysesthesias, tend to persist longer than the gastrointestinal symptoms and have been reported up to years later.

Differential Considerations. Ciguatera fish poisoning should be strongly considered in patients with a combination of gastrointestinal and neurolologic symptoms, particularly dysesthesias. Cold allodynia and marked worsening of the symptoms with alcohol ingestion are highly suggestive of ciguatera toxicity.

The disease sometimes is misdiagnosed as acute gastroenteritis with “hyperventilation syndrome” because of the combination of gastrointestinal symptoms and paresthesias, particularly when they occur about the mouth and acral areas. Similarly, manifestations of ciguatera toxicity sometimes have been ascribed to malingering because the paresthesias often are transient and vague and lack traditional dermatome patterns.

Other disorders that should be considered in the differential diagnosis include paralytic or neurotoxic shellfish poisoning, eosinophilic meningitis, botulism, organophosphate insecticide poisoning, and tetrodotoxin poisoning.

Management. Treatment is primarily supportive. Intravenous fluids are given to replace volume losses from vomiting and diarrhea, and analgesics are given as needed. In severe cases, the toxin may exhibit some anticholinesterase activity, manifested as bradycardia and hypotension, which can be treated with atropine and dopamine. Patients must be told to abstain from alcohol in any amount until symptoms have completely resolved.

Pruritus may be managed with a histamine H_1 receptor antagonist such as cetirizine (Zyrtec) at a dosage of 10 mg once
daily. Amitriptyline, 25 mg twice a day, can bring about a dramatic reduction in both the pruritus and the dysesthesias, two of the most disturbing and protracted symptoms.

Intravenous mannitol has historically been an accepted treatment for ciguatera poisoning. The rationale for its use was based on data compiled from one uncontrolled study of 24 patients, one nonrandomized study, one nonblinded study, and anecdotal reports. More recently, a controlled, randomized double-blinded study of 50 adults found no difference in symptomatic improvement between patients who received normal saline and those who received mannitol. In addition, studies of ciguatoxin-intoxicated animals showed that mannitol did not reverse the effects of ciguatoxin. On the basis of this information, mannitol probably is not an effective therapy for ciguatera poisoning.39

**Enterotoxigenic Escherichia coli**

**Epidemiology.** Enterotoxin-producing E. coli, or enterotoxigenic E. coli (ETEC), is recognized as a major cause of acute diarrheal disease throughout most of the world. It is a major cause of diarrhea in persons traveling to underdeveloped areas. The disease has been most intensely studied in North American visitors to Latin America, where it occurs in 17 to 70% of travelers studied, often incapacitating them or forcing a change in their plans.40 ETEC is increasingly recognized as a cause of food-borne illness in developed countries, including the United States.41

Infection is acquired from contaminated food or drink. Unpeeled fruits, leafy vegetables, unsanitary drinking water, and ice prepared from impure water are the most common sources. Most tourists are careful about their food and drink, but there seems to be a poor correlation between individual eating habits and the incidence of traveler’s diarrhea.

**Pathophysiology.** For an E. coli strain to cause diarrhea, it must possess both a surface factor that allows colonization (although not invasion) of the small intestine and the ability to secrete an enterotoxin that causes the outpouring of fluids and electrolytes into the small bowel lumen. The enterotoxin-induced secretion occurs in the absence of any demonstrable histologic damage to intestinal epithelial cells or to the capillary endothelial cells.42

*Escherichia coli* produces both heat-labile and heat-stable toxins. The heat-labile enterotoxin is similar to choleratxin in that it binds to specific receptors on the surface of the intestinal epithelial cell, allowing translocation of an A subunit into the cell. The A subunit modifies host cell signals, resulting in the dysregulation of sodium and chloride secretion, disturbances of ion transport, and intestinal water loss. The heat-stable toxin exerts its effect through the stimulation of guanylate cyclase in mucosal cells and tends to have a more rapid onset of action. Either or both toxins can be produced by any enterotoxic strain of *E. coli*. The intestinal fluid losses are qualitatively identical to those in cholerat and other toxigenic diarrheas.42

**Clinical Presentation.** After an incubation period of 24 to 72 hours, an abrupt onset of watery diarrhea occurs. Severity varies, with the illness ranging from a fulminant, cholera-like disease to the much more common and milder *turista*, in which the symptoms of mild, watery diarrhea and abdominal cramps are more troublesome than life-threatening. Fever is unusual. Vomiting occurs in fewer than one half of affected adults and is seldom responsible for significant fluid losses. Even in severe cases, the diarrhea seldom lasts longer than 48 to 72 hours, and the response to either oral or intravenous fluids is uniformly good. Milder disease generally subsides more gradually, occasionally persisting for 1 week or longer. Virtually all persons recover completely without long-term sequelae.

E. coli enterotoxin–induced disease should be suspected when a child or adult has frequent, watery diarrhea and few other symptoms. It often is passed off as “mild, nonspecific gastroenteritis” and resolves spontaneously. Anyone who acquires toxigenic diarrhea while visiting a developing nation probably has this disease. ETEC is by far the most common cause of traveler’s diarrhea.

**Diagnostic Strategies.** No easy, rapid means of laboratory diagnosis of ETEC infection exists. Methods that rely on identification of specific *E. coli* serotypes are unreliable because *E. coli* is part of the normal colonic flora, and its ability to produce enterotoxin is not restricted to any specific serotype. Methods based on detection of the heat-stable and heat-labile toxins using real-time PCR assay have been developed but are not clinically available. Stool preparations show no erythrocytes or leukocytes.

**Management.** Because ETEC infection is almost always a self-limited disease, no treatment other than maintaining hydration is required. However, if the organism is identified while symptoms are still active, or if the patient is traveling in an endemic area, antibiotics can give afford clinical relief. For milder symptoms, a single dose of ciprofloxacin 750 mg by mouth in addition to loperamid should be effective. For more severe symptoms, TMP-SMX 160 mg/800 mg or standard doses of a fluoroquinolone for 3 days should eradicate the organism.3

**Clostridium difficile**

**Antibiotic-Associated Enterocolitis**

**Epidemiology.** *Clostridium difficile* is an anaerobic spore-forming gram-positive bacillus that was first linked to enteritis in 1978. It has been associated with a range of illnesses from asymptomatic colonization to severe diarrhea, pseudomembranous colitis, toxic megacolon, intestinal perforation, and death.45 *C. difficile* can be cultured from the stool of up to 50% of healthy infants and approximately 3% of healthy adults.7 The disease is unique in that an organism normally found in the colon causes illness primarily during or after the administration of antimicrobial agents. Colitis can occur as a result of oral or parenteral administration of most antimicrobial drugs, including quinolones, clindamycin, lincomycin, ampicillin, cephalosporins, tetracycline, penicillin, chloramphenicol, sulfa products, and erythromycin. Other risk factors, in addition to recent use of antimicrobials, include age older than 65 years, severe underlying illness, nasogastric intubation, use of antilulcer medications, and prolonged hospital stay.45 Infection with this organism occurs primarily in adults. Most cases of *C. difficile* colitis occur in patients who are hospitalized or reside in long-term care facilities. Stool carriage rates reach 16 to 35% in hospitalized patients owing to transfer of organisms by the hands of hospital personnel or from patient to patient.46 Occasional nosocomial infections occur in the absence of antibiotic therapy.7

During the past several years, an increase in the incidence and severity of *C. difficile*–associated colitis has been noted, along with recognition of a new strain designated NAP1/027 (toxinotype III, North American pulsed field gel electrophoresis type 1, PCR ribotype 027). This strain has been associated with outbreaks in Canada, Europe, and the United States. Data from the CDC indicate that hospitalizations with a discharge diagnosis of *C. difficile* colitis have increased, from 31 per 100,000 population in 1997 to 61 per 100,000 in 2003.43

**Pathophysiology.** *C. difficile* bacteria proliferate when the normal bowel flora is substantially reduced by antibiotic therapy. The organisms must then produce sufficient quantities of toxin for the disease to occur. *C. difficile’s* primary virulence factors are known as toxin A and toxin B. Toxin A attracts neutrophils
and monocytes, and toxin B disrupts colonic epithelial cells, both leading to watery diarrhea, colitis, and pseudomembrane formation. In persons who are colonized with *C. difficile* without experiencing colitis, higher levels of antibody to toxin A have been documented, and development of clinical disease is less likely. In those in whom colitis does develop, higher levels of anti-toxin A antibody are associated with a shorter duration of illness and decreased recurrence rate. \(^44\) The incubation period has not been well established. \(^43\)

On histologic examination, the mucosa is hyperemic and edematous. Raised, yellowish-white plaques, loosely adherent to the mucosa, occur in patches, primarily in the rectosigmoid area, but can occur in any part of the colon. The disease was previously named “pseudomembranous enterocolitis” because of these pseudomembrane-like plaques.

**Clinical Presentation.** Symptoms may appear during the course of antimicrobial therapy or commonly up to 3 or 4 weeks after discontinuation of antibiotics. Of interest, *C. difficile* has been reported to produce illness as late as 6 months after completion of antibiotic therapy. The clinical presentation is highly variable. Most often, patients present with mild to moderate non-bloody diarrhea associated with lower abdominal cramping and few systemic symptoms. Because the toxin alters the intestinal mucosa, the illness can manifest more like an invasive diarrhea than a toxigenic one, with fever, nausea, dehydration, severe crampy abdominal pain, distention, and profuse watery stools. Occult blood in the stool may be a feature, although hematochezia is uncommon. Fecal leukocytes usually are present. Children tend to have more severe infections than those seen in adults. *C. difficile* colitis is associated with a mortality rate of 6 to 30% when pseudomembranous colitis is present. \(^44\)

**Diagnostic Strategies.** A variety of diagnostic tests are available for the detection of *C. difficile*. The historical “gold standard” modality is the cell cytotoxicity assay, in which stool is cultured on suitable medium and observed for the cytotoxic effect of toxin B. This test is 94 to 100% sensitive but requires 48 to 72 hours for completion. Stool toxin assays are now the primary method used to diagnose *C. difficile* infection. \(^7,43,44\) Enzyme-linked immunosorbent assay (ELISA) for toxins A and B initially showed low sensitivity, but this has improved sufficiently that now most hospitals use ELISA testing, with a 2-hour turnaround time, as the preferred method. Stool cultures can confirm the presence of *C. difficile* in the feces of patients with antibiotic-associated enterocolitis (AAC). However, a positive stool culture result is not diagnostic because *C. difficile* is often present in the feces of normal subjects (especially infants) or in persons receiving antibiotics who do not have an enteritis. Cultures are seldom used clinically but often are part of epidemiologic studies. \(^7,43,44\) In patients with typical history and physical examination findings, a tentative diagnosis can be made by sigmoidoscopy or colonoscopy.

**Differential Considerations.** It is important to differentiate *C. difficile* colitis from simple antibiotic-associated diarrhea. Three percent to 10% of all patients treated with antibiotics, particularly children, develop diarrhea not associated with *C. difficile* toxin. These patients experience mild, watery diarrhea and no associated constitutional symptoms or evidence of a cytotoxic toxin–induced colitis.

**Management.** In early studies, 15 to 23% of patients who had *C. difficile* colitis experienced spontaneous resolution within 48 to 72 hours of discontinuing the offending antibiotic. \(^44\) If discontinuing the antibiotic does not resolve the diarrhea, or if the diarrhea is severe, antibiotic treatment should be started promptly. Either oral metronidazole or oral vancomycin can be used. The dosage of metronidazole is 250 mg orally four times daily for 10 to 14 days. Metronidazole also is effective when administered by the intravenous route. Doses of vancomycin ranging from 125 to 500 mg orally four times daily have been equally effective. \(^44\) Intravenous vancomycin generally is not effective because it does not reach effective intraluminal concentrations.

Initial trials comparing metronidazole and vancomycin found similar response rates of approximately 90%. In more recent studies, approximately 78% of patients treated with metronidazole had an initial response to therapy, and approximately one third of these had recurrence of disease, for an overall response rate of approximately 50%. Because vancomycin is much more expensive than metronidazole and because of concerns about emerging vancomycin resistance, oral metronidazole is the agent of choice for treatment in patients with mild disease, and oral vancomycin is reserved for patients who do not respond to metronidazole therapy or for those who are moderately to extremely ill at the time of presentation. \(^45\)

Patients generally become afebrile and show clinical improvement within 36 to 72 hours; the diarrhea resolves over 5 to 7 days, even though results of toxin assays and stool cultures may remain positive for weeks. From 8 to 50% (average, 25%) of patients suffer a relapse regardless of the antibiotic chosen, its dosage, or the duration of treatment, and the recurrence rate is increasing. Risk factors for recurrent disease include new exposure to antibiotics, age older than 65 years, severity of underlying disease, low serum albumin, need for admission to an intensive care unit, and hospital stay of 16 to 30 days. Nearly all of these patients will respond to another course of antibiotic therapy. \(^44\)

Adding the yeast *Saccharomyces boulardii*, 500 mg orally twice daily for 4 weeks, to antibiotic treatment has been shown to dramatically decrease the number of recurrences of *C. difficile*–associated disease in patients with previous episodes. However, no benefit is seen when *S. boulardii* is given to patients with an initial episode. \(^44\) No serious adverse reactions have occurred with the use of *S. boulardii*. \(^44\)

Although toxicity from parenteral vancomycin is common, no adverse effects have been reported with its oral use in the treatment of *C. difficile* colitis. Antimotility or constipating agents are contraindicated in these patients because of the risk of toxic megacolon and the possibility of increasing the level of cytotoxic toxin in the colon. \(^44\)

**ACUTE VIRAL GASTROENTERITIS**

**Etiology and Epidemiology.** Viral gastroenteritis is the second leading cause of illness in the United States. Although several virus families have been implicated, including caliciviruses, coronaviruses, and parvoviruses, two have predominated in the past decade. Noroviruses, which include the Norwalk virus, are primarily responsible for disease in adults and older children, whereas human reovirus–like agents, also called *rotaviruses*, cause most diarrheal disease in infants and young children. Worldwide, rotavirus infection causes 600,000 to 875,000 deaths annually and is responsible for 6% of deaths in children younger than 5 years of age. In the United States, rotavirus infection is the leading cause of hospitalization for gastroenteritis and precipitates 600,000 physician visits, 50,000 admissions, and approximately 20 deaths each year. Rotaviruses also cause epidemics in adults, especially those in contact with sick children. \(^7\)

These viruses have a low infectious dose, and attack rates may reach 50%. The incubation period is short, so explosive outbreaks are common. Norovirus is transmitted by several routes and is relatively stable in the environment, making this infection particularly prone to spread of infection. It is esti-
Viral gastroenteritis occurs primarily in two outbreaks of gastroenteritis in industrialized countries. Both viruses can be transmitted from person to person by the fecal-oral route, but water- or food-borne outbreaks also are common. Sources in large reported outbreaks of norovirus infection have included municipal or semipublic water supplies, bodies of water used in recreational swimming, stored water on cruise ships, cafeteria sandwiches, food handlers, and shellfish. The ingestion of raw oysters has caused many large outbreaks. The CDC estimates that 50% of all food-borne outbreaks of gastroenteritis are attributable to noroviruses.7 Nosocomial spread of infection also is common. Astrovirus and picornaviruses are common causes of diarrhea in HIV-infected patients.7

Pathophysiology. Viruses distort the absorptive cells of the microvilli of the small bowel, decreasing their absorptive surface and causing diarrhea from decreased absorption of fluid and electrolytes. Viral nonstructural proteins also may act as enterotoxins, promoting active chloride secretion into the bowel lumen. The histologic picture resembles that with tropical sprue, and transient malabsorption of fats and sugars, which may persist for a week or more after infection, occurs in patients with viral gastroenteritis.45

Diarrheal stools in viral disease contain more sodium, chloride, and bicarbonate than do normal stools, but these abnormalities are not comparable with the almost isotonic fluid loss of bacterial toxin–induced diarrhea. Potassium loss usually is not significant unless symptoms are prolonged.

Clinical Presentation. Viral gastroenteritis occurs primarily in two epidemiologically distinct clinical forms. Outbreaks caused by rotaviruses usually are sporadic, occasionally are epidemic, and typically occur in the winter months in infants and children 6 to 24 months of age. The incubation period is 24 to 72 hours, followed by abrupt onset of vomiting, watery diarrhea, and low-grade fever but little or no associated abdominal pain. Vomiting is a prominent and constant early manifestation of rotavirus enteritis but rarely persists beyond the first 36 hours. The diarrhea generally lasts for 4 to 7 days and may be followed by steatorrhea in approximately 20 to 40% of patients. Many children become significantly dehydrated, requiring hospitalization and intravenous fluid replacement, but the disease rarely is life-threatening in developed countries.

Overt clinical disease can occur among family and adult contacts of ill children, but it is uncommon. Most adults with rotavirus infections are asymptomatic. When symptoms do occur, they usually are mild, perhaps because these episodes represent reinfections; 60 to 90% of older children and adults have antibodies to rotaviruses.45

The second clinical entity is characteristically epidemic and is responsible for family and community-wide outbreaks of gastroenteritis among school-aged children, family contacts, and adults. This form generally is caused by the Norwalk virus. After an incubation period of 20 to 36 hours, diarrhea, nausea, and mild abdominal cramps occur. Vomiting is not prominent. Fever typically is absent. Anorexia, headache, malaise, and myalgias may be present. The illness is self-limited, usually lasting only 24 to 48 hours. Most affected adults have mild symptoms and do not seek medical attention.7,45

Diagnostic Strategies. The diagnosis of rotavirus gastroenteritis should be considered in children with significant vomiting, diarrhea, low-grade fever, moderate dehydration, and a normal white blood cell count, especially in those 6 to 24 months of age who become symptomatic during the winter months. An elevated blood urea nitrogen level and a compensated metabolic acidosis are common findings. Serum electrolyte studies indicate that the dehydration usually is isotonic. In adults, the diagnosis of viral gastroenteritis usually is one of exclusion. Viral enteritis is the likely diagnosis when a patient has mild intestinal symptoms, does not appear ill, and further history and physical examination uncover no reason to suspect a bacterial pathogen, inflammatory disease, or any other cause. No investigation beyond the physical examination usually is required. Some of these patients may actually have mild bacterial infections, but these also generally are self-limited, and treatment is not different.

A laboratory diagnosis can be made by demonstration of the viruses in stools by electron microscopy or various methods used for the detection of viral antigens, such as latex agglutination, ELISA, or reverse transcriptase–PCR techniques. With rotavirus infection, large numbers of viruses are present in the stools, and these antigen detection methods are quite sensitive and specific. Rotavirus testing probably is indicated only in more serious cases of diarrhea. Fecal leukocytes and erythrocytes are not found in cases of viral gastroenteritis.7

Management. The most important aspect of therapy for acute viral gastroenteritis is fluid replacement. Many children require hospitalization for intravenous fluid and electrolyte repletion. No specific antiviral therapy is indicated. Use of antidiarrheal agents is not recommended in children. In adults, they generally are not needed but may provide some symptomatic relief. Because viral spread is primarily by the fecal-oral route, scrupulous hand washing and other hygienic practices are the best preventive measures.

A live tetravalent vaccine against rotavirus was approved for use in infants in 1998 but was withdrawn from the market in 1999 owing to a temporal association with intussusception. Rotateq is a newer oral, liquid live pentavalent vaccine that was licensed in the United States in 2006 and is now part of the annual recommended immunization schedule for all infants at ages 2, 4, and 6 months.

Parasitic Gastrointestinal Infection

Organisms that commonly cause protozoal enteritis are summarized in Table 92-4. As a group, parasitic pathogens are associated with more prolonged illness than that characteristic for bacterial or viral pathogens. The clinician should consider the possibility of a parasitic infection in patients with diarrhea that persists for longer than 2 weeks, especially in immunocompromised persons, travelers, and residents of developing countries.

Coccidial Infections

Cryptosporidium and Isospora belli Infections

Epidemiology. Cryptosporidium and Isospora are intestinal protozoa parasites that commonly cause diarrhea in the young of many animal species. In humans, cryptosporidiosis is a worldwide problem, most often seen in persons who handle animals, children in day care centers, healthy homosexual men, and immunocompromised patients.7,46 Cryptosporidium has been the most common cause of chronic diarrhea in persons with AIDS, although the incidence has decreased in the U.S. AIDS population with the use of highly active antiretroviral therapy (HAART).47 Congenital immunodeficiency and treatment with cancer chemotherapeutics or other immunosuppressive drugs are additional predisposing factors. The organism is highly infectious and is easily transmitted among nosocomial, household, and day care contacts or in any facility in which personal hygiene is poor.47 In addition to zoonotic and person-to-person spread, indirect transmission occurs by exposure to
Epidemiologic Presentation.

Infection may be commensal or non-pathogenic. The clinical presentations of cryptosporidiosis are characterized by mild to profuse watery diarrhea, crampy abdominal pain, anorexia, nausea, malaise, weight loss, and flatulence. The diarrhea and abdominal pain often are exacerbated by eating. Immunosuppressed patients (especially HIV-infected patients with CD4+ counts less than 200/mm³) can experience enormous stool fluid losses: 3 to 4 L/day is common, and losses may reach 10 to 20 L/day. Physical examination usually reveals only signs of dehydration. Minimal diffuse abdominal tenderness may be elicited by palpation, and fever and leukocytosis are uncommon. Eosinophilia is not a feature. Findings on stool examination for blood or leukocytes are almost uniformly negative in adults but occasionally are positive in children.

The patient's immune status is the primary determinant of whether the infection is self-limited or persistent. Diarrhea in immunocompetent persons usually resolves after 1 to 3 weeks, but it can continue longer or become chronic. In immunodeficient patients, especially those with AIDS, chronic, persistent diarrhea is common, causing significant discomfort and morbidity unless the infection is responsive to treatment.

Asymptomatic infections can occur from either Cryptosporidium or Isospora, and a carrier state has been demonstrated for Cryptosporidium. In a U.S. study of immunocompetent patients who underwent upper endoscopy for a variety of reasons, 13% were found to harbor cryptosporidia in the second portion of the duodenum. None of the patients had diarrhea.

Pathophysiology. The pathophysiology is the same for both Cryptosporidium and Isospora. Disease is acquired by ingestion of oocysts. Excystation occurs, and sporozoites attach to the surface of intestinal epithelial cells of the terminal ileum and proximal colon; no tissue invasion occurs. Profuse fluid loss results from a combination of active chloride secretion and malabsorption. A specific enterotoxin has not been identified, although up-regulation of a variety of proinflammatory cytokines, chemokines, and neuropeptides has been observed. In cryptosporidiosis, a biliary reservoir may contribute to chronicity of the infection and inability to eradicate the organism.

Clinical Presentation. The clinical presentations of cryptosporidiosis and of isosporiasis are indistinguishable and highly variable. After an incubation period of approximately 1 week, symptoms may develop insidiously or suddenly. Infection is characterized by mild to profuse watery diarrhea, crampy abdominal pain, anorexia, nausea, malaise, weight loss, and 5-10% of U.S. population, malabsorption syndromes or commensal.

AIDS, acquired immunodeficiency syndrome.
in several studies. A PCR-based assay for Cryptosporidium has been developed but is not yet available in clinical laboratories.\textsuperscript{7,46}

**Management.** In immunocompetent persons, Cryptosporidium infection generally is self-limited; symptomatic therapy and fluid replacement are sufficient. Initial management should focus on replacement of fluid and electrolytes, by the oral route if possible. Antimotility agents such as loperamide or the combination diphenoxylate/atropine (Lomotil) can decrease stool output in persons with mild to moderate illness. For immunocompetent patients with persistent disease, nitazoxamide 100 to 500 mg every 12 hours has been approved by the U.S. Food and Drug Administration (FDA) and has proved to be effective in adults and children older than 1 year of age.\textsuperscript{46} Immunocompetent patients shed oocysts in the stools when symptomatic and continue to do so for up to 6 weeks after resolution of their clinical illness, creating a public health risk. Oocyte shedding resolves more rapidly in those treated with nitazoxamide.\textsuperscript{46}

Treatment of cryptosporidiosis in immunocompromised patients is more challenging. The most successful interventions occur when the underlying immunodeficiency can be reversed. In patients taking immunosuppressive agents, immune function generally recovers if the drugs can be discontinued. Patients with AIDS and CD4\textsuperscript{+} counts below 200/µL sometimes respond dramatically if immune function is restored through institution of HAART.\textsuperscript{46} Patients severely infected with Cryptosporidium often are fecally incontinent, with large numbers of infectious oocysts in the stool, so strict enteric precautions are necessary to prevent nosocomial spread. If enhancing the immune system fails and symptoms continue to be severe, nitazoxamide 0.5 to 1 g twice daily combined with antidiarrheals may be used, although evidence is lacking for the efficacy of nitazoxamide in HIV-infected patients. Paromomycin (Humatin, 500 to 750 mg three or four times daily) also is sometimes used to ameliorate cryptosporidiosis, particularly in combination with azithromycin, but no good evidence exists that these drugs are routinely effective.\textsuperscript{46}

In contrast with cryptosporidiosis, isosporiasis responds promptly to antibiotic therapy. The treatment regimen of choice for isosporiasis in immunocompetent adults is TMP-SMX 160 mg, 800 mg twice daily for 10 days. In immunocompromised adults, the dosage is increased to four times daily for 10 days and then extended with twice-daily dosing for 3 weeks. In patients with sulfonamide sensitivity, pyrimethamine 50 to 75 mg daily may be effective.\textsuperscript{7} Chronic suppressive therapy with either twice-daily doses of TMP-SMX or daily doses of pyrimethamine only is required, because Isospora infection recurs in more than 50% of patients.\textsuperscript{3}

Patients seen in the ED in whom stool examination for Cryptosporidium or Isospora should be contacted for appropriate management. Recovering patients require only an explanation of the diagnosis and its ramifications. Patients who are not recovering and those who are known or thought to be immunosuppressed should receive appropriate treatment and referral for follow-up care. Cryptosporidiosis is a nationally notifiable disease.

**Cyclospora cayetanensis Infection**

**Epidemiology.** Cyclospora is a coccidial parasite widely distributed throughout tropical and subtropical areas of the world that produces disease similar to that caused by Cryptosporidium and Isospora. In Nepal, Cyclospora organisms have been found in up to 11% of patients with diarrheal disease.\textsuperscript{49} North American outbreaks have been traced to contaminated foods, primarily fresh fruit such as raspberries grown in Guatemala, fresh salads containing snow peas from Guatemala, fresh basil preparations, and mesclun lettuce; foreign travel; and contaminated water supplies.\textsuperscript{50} Cyclospora infects all classes of vertebrates, reptiles, and rodents, and the vast majority of cases occur during the spring and summer seasons, often in large outbreaks.

**Pathophysiology.** The exact mode of Cyclospora transmission and mechanism of disease is not completely understood. The organism passes from the human gastrointestinal tract as an oocyst that must sporulate in order to become infective. Sporulation requires several days to weeks outside the human host; therefore, the disease is not transmitted from person to person and is not likely to be transmitted by infected food handlers. Recent work in Nepal suggests that domestic pets and farm animals may serve as intermediate hosts.\textsuperscript{51} Histologic examination shows flattening of the villi and thickening of the base-ment membrane in the duodenum with intracellular parasites identified in jejunal biopsies, but it is unknown whether symp-toms are toxin-induced or secondary to direct infection of the small bowel.\textsuperscript{50} As with other parasitic diseases, immunocompromised patients are affected more frequently than immunocompetent hosts.\textsuperscript{51}

**Clinical Presentation.** The average incubation period is 1 week.\textsuperscript{50} Typically, the patient presents with an acute onset of explosive watery diarrhea and abdominal cramps. Thirty percent of patients report fever during this initial phase. Severe diarrhea subsides within 1 to 3 days and is followed by a period of intermittent mild diarrhea and marked anorexia and fatigue, which distinguishes this from other parasitic disorders. Weight loss is almost invariable, as is malabsorption of xylose.\textsuperscript{50} Constitutional symptoms are relatively mild, and fever is uncommon. Fecal leukocytes are absent. The disease generally is self-limited in immunocompetent persons but may last as long as 2 to 6 weeks, and relapsing diarrhea is common. Sustained fatigue and weight loss are especially characteristic of cyclosporiasis. These findings are noted in approximately 90% of patients and should prompt consideration of the diagnosis in the setting of outbreaks or history of foreign travel.\textsuperscript{51}

**Diagnostic Strategies.** The clinical picture may be suggestive, but finding oocysts in the stool is required to confirm the diagnosis. Stool specimens submitted for ova and parasite testing are not routinely examined for Cyclospora unless specifically requested. The oocysts measure 8 to 10 µm in diameter, approximately twice the size of Cryptosporidium oocysts. Oocysts can be identified by modified acid-fast stain, yet the inexperienced microscopist may overlook them or find Cyclospora difficult to distinguish from Cryptosporidium. False-negative and false-positive results on microscopic examination are common. Microscopic examination is greatly facilitated by stool concentration techniques.\textsuperscript{50} Cyclospora also can be identified by stool PCR testing, although this technique is not widely available in U.S. hospitals.

**Differential Considerations.** The primary confusing organism is Cryptosporidium, because the symptoms of infection with the two pathogens often are indistinguishable. Cryptosporidium tends to be associated with animal contact, exposure in day care centers, and immunocompromised status. Aeromonas hydrophila infection also should be considered in the differential diagnosis.

**Management.** The disease tends to be self-limited in immunocompetent persons, but treatment with sulfa medications is very effective for cyclosporiasis, in contrast with cryptosporidiosis. The drug regimen of choice consists of double-strength TMP-SMX one tablet twice daily for 7 days in immunocompetent patients, and one tablet four times daily for 10 days, followed by one tablet three times per week, in patients with AIDS. The pediatric dose is TMP 5 mg/kg plus SMX
25 mg/kg twice daily for 7 days. Thorough washing of fresh produce before consumption decreases but does not eliminate the risk of transmission. Irradiation may be a future solution.50,51 Cyclosporiasis is a reportable disease.

Giardiasis

Epidemiology. Giardia is one of the most common causes of parasitic diarrheal outbreaks in the United States.7,46 The mode of transmission in large outbreaks is contamination of municipal water supplies with cyst-infested feces from humans or animals, particularly beavers or muskrats, but also dogs, raccoons, and other animals. Campers and backpackers commonly acquire giardiasis, called “backpacker’s diarrhea,” from drinking fecally contaminated water from the “pristine” mountain streams.46 Only rarely is Giardia infection transmitted by contaminated food.

Giardia can be spread by sexual or other close person-to-person contact in which fecal contamination may occur, particularly among homosexual men, and in day care centers and institutions for the mentally challenged. The prevalence is 4 to 7% in the general U.S. population, 5 to 20% in homosexual men, and 25 to 50% in children attending day care centers.46

Many cases of acute symptomatic giardiasis in the United States are found in persons returning home from travel elsewhere. Travelers to any developing country can acquire giardiasis, but it is especially feared in those who visit the republics of the former Soviet Union, the Caribbean states, and Latin America, where the water supplies appear to be heavily contaminated with Giardia cysts.52 Small groups traveling to the former Soviet Union, particularly the city of Leningrad, have experienced attack rates approaching 60%, and the disease is ruefully known among its victims as “the Trotskys.” More recently, a Swedish study of giardiasis in returning travelers found that highest attack rates occurred in those returning from the Indian subcontinent, east Africa, and west Africa.53

Patients with decreased gastric acidity, for any reason, are more susceptible to Giardia infection. Giardiasis also is more frequent in patients with various immunoglobulin deficiencies; a relative deficiency of intestinal immunoglobulin A (IgA) may be the reason.

Pathophysiology. Giardia trophozoites infect the duodenum, jejenum, and upper ileum. Encystation occurs in the gut lumen, and cysts passed in the feces remain viable for long periods. After the cysts are ingested by the next host, excystation to the active trophozoites occurs in the proximal small bowel, completing the parasite’s life cycle. The trophozoites multiply rapidly. A single diarrheal stool may contain billions of parasites or hundreds of millions of cysts. The trophozoites are capable of superficial invasion of the mucosa, but malabsorption probably causes most symptoms.

Clinical Presentation. Many patients harboring Giardia are asymptomatic. The most common symptoms of acute infection are abdominal distention (69%), colicky pain (70%), flatulence (74%), and frequent episodes of explosive diarrhea (89%) producing pale, loose stools that often are offensive-smelling. Audible borborygmi is a classic feature. The serum white blood count usually is normal, and eosinophilia is not seen. The onset typically is sudden, following an incubation period of 1 to 3 weeks. Symptoms may resolve within 7 to 10 days or continue intermittently and produce a malabsorption-like illness, particularly in patients with an immunoglobulin deficiency. The infection resolves spontaneously within 6 weeks in 85% of patients.

Diagnostic Strategies. Routine tests (e.g., blood counts, electrolyte panel, radiographic studies) generally are not helpful. Eosinophilia is not seen. Stool examination is the primary means of diagnosis. In the acute phase of Giardia infection, rapid bowel transit allows trophozoites as well as the more hardy cystic form of the parasite to appear in the stool. Trained observers using standard stool examination techniques will readily identify Giardia in more than 95% of acute cases if three or more stool specimens are studied. Detecting Giardia in cases of subacute, chronic, or asymptomatic infection, however, can be difficult. The trophozoites may be passed only intermittently and in small numbers. Concentration techniques should be used to improve the chance of finding the cysts in the stools. Diagnosis may require small bowel sampling techniques such as duodenal-jejunal aspiration by endoscopy or biopsy of duodenal-jejunal tissue. Giardia antigen tests using immunofluorescence ELISA, nonenzymatic immunoassays, or direct fluorescent antibody (DFA) techniques are replacing microscopic examination as the strategy of choice. The per-specimen cost is similar to that for microscopy; sensitivity is 85 to 98% and specificity 90 to 100%.46

Differential Considerations. Entamoeba hominis, a flagellate parasite like Giardia, can produce an intestinal infection that mimics giardiasis. Enteroanoma infection most commonly affects children and homosexual men. Even when all techniques fail to confirm a clinically suspected case of giardiasis, an empirical diagnosis can be supported by a successful trial of appropriate antibiotics.

Management. The treatment regimen of choice has historically been metronidazole, a 5-nitroimidazole drug, 250 mg three times daily for 7 days for adults or 5 mg/kg three times daily (maximum 250 mg three times daily) for 7 days for children.3,46 Metronidazole has an efficacy rate of 80 to 95%. Tinidazole is another 5-nitroimidazole agent that is FDA approved for the treatment of giardiasis. Some experts consider tinidazole a first-line agent because it can be given as single-dose therapy. When given in a single 2-g dose (50 mg/kg in children), tinidazole achieves a cure rate of approximately 90%. Furazolidone is the only alternative drug available as a suspension, which may be helpful in treating children. Its cure rates average only 80%, however. The recommended dosage is 100 mg four times daily for adults or 1.5 mg/kg four times daily for children, up to the adult dose, for a total of 7 to 10 days. Nausea and vomiting are common side effects, and rarely a hemolytic anemia develops in patients with glucose-6-phosphate dehydrogenase deficiency.56

Treatment of asymptomatic infections is controversial and best determined on a case-by-case basis. Asymptomatic cyst passers, especially children and food handlers, pose a threat of infection to others and are at risk for the development of intermittent chronic symptoms. Treatment of asymptomatic carriers can theoretically reduce the risk of spread. In heavily infected endemic populations, reinfection is practically universal after 3 months, and treatment is not useful or cost-effective.54

Giardiasis must be considered a family infection. Strict adherence to hand washing is important, especially after using the toilet, playing with pets, or changing diapers. To prevent reinfections, other household members and sexual contacts should be examined and, if found to harbor the parasite, treated appropriately.56

Acute Intestinal Amebiasis

Epidemiology. Entamoeba histolytica is a ubiquitous organism infecting at least 10% of the world’s population but originally thought to cause clinical disease in only 10% of persons who carry it. This number probably is an underestimate, however, because recent studies have confirmed the presence
of a morphologically indistinguishable ameba, *E. dispar*, as a separate nonpathogenic species that also colonizes the human gut and probably is responsible for a majority of asymptomatic infections originally attributed to *E. histolytica*. Distinguishing between the two organisms can be accomplished using ELISA or PCR assay, with PCR testing slightly more reliable. Worldwide, approximately 50 million symptomatic cases occur each year, resulting in 100,000 fatalities. In the United States, high-risk groups include travelers, homosexual men, patients with AIDS, and institutionalized persons. Most cases acquired in the United States are asymptomatic; acute amebic dysentery is rare and most often occurs in travelers returning from developing countries in which the disease is endemic.

*Entamoeba histolytica* exists in trophozoite and cystic forms. The trophozoites infect the colon and may produce symptomatic disease. Infectious cysts are passed in the stool and are highly resistant to environmental factors. Transmission usually occurs through ingestion of cysts present in fecally contaminated food or water. Homosexual men commonly acquire amebic infection from cysts ingested through anal-oral sexual practices. When these patients present with diarrhea, a diligent search for other organisms should be completed before symptoms are ascribed to amebic infection. Co-infection with other enteric pathogens occurs frequently in homosexual men.

**Pathophysiology.** The factors that determine whether infection with *E. histolytica* will be commensal or invasive are poorly understood. Variable strain virulence and host susceptibility are determinants. In young children, pregnant women, persons with malnutrition or underlying systemic disease, or persons taking corticosteroids, amebiasis often is more fulminant.

Invasive trophozoites characteristically produce colonic ulcerations that on histologic examination are seen to have rounded or punched-out margins and are elevated by a submucosal inflammatory reaction from the advancing trophozoites. The ulcer bases are covered with whitish or yellowish exudate. Usually, no diffuse mucosal inflammation exists in areas between ulcers. Should diffuse inflammation occur, however, the picture becomes indistinguishable from that of idiopathic ulcerative colitis or Crohn’s disease. Less than 1% of infections will spread outside the intestines. Gastrointestinal complications include severe bleeding, toxic megacolon, intussusception, stricture, obstruction, and perforation. Extraintestinal complications include liver and brain infection, as well as pleural or pericardial effusions.

**Clinical Presentation.** In many patients, *E. histolytica* lives as a commensal, without producing symptoms. Acute amebic dysentery manifests after an incubation period as short as 1 week or as long as 1 year. The onset is abrupt, with fever; severe abdominal cramps; profuse, bloody diarrhea; and tenesmus. Chronic amebic colitis is the common symptomatic form, for which the onset is gradual. Usually, intermittent diarrhea is present, with two to four foul-smelling stools daily, often containing blood-streaked mucus. Vague abdominal cramps, flatulence, weight loss, and low-grade fever are present. Symptomatic periods may alternate with asymptomatic periods lasting for months to years. The only physical finding may be slight right lower quadrant tenderness to palpation and occasional tender hepatomegaly. The diagnosis is elusive because cysts or trophozoites are difficult to detect; inflammatory bowel disease is a common misdiagnosis, and steroid therapy may exacerbate the symptoms.

The stools of patients with symptoms contain mucus and leukocytes, although not in large quantity and numbers. Eosinophilia is not seen except in rare cases of ameboma. Liver function test results generally are normal unless the disease is complicated by liver abscess, which is the most common serious complication of amebic colitis.

**Diagnostic Strategies.** Definitive diagnosis of intestinal amebiasis historically relied on microscopic identification of the organisms in the stools. Microscopic examination limited to a single stool sample can miss almost one half of infections; at least three fresh samples should be submitted. The examination must precede the administration of antibiotics, antidiarrheal agents, antacids, or enemas, or before the performance of radiographic procedures using barium sulfate. All of these agents destroy trophozoites or distort cysts, thereby interfering with the recovery of amebas. A rectal biopsy specimen or mucosal exudate obtained at sigmoidoscopy may reveal the amebas, even when multiple previous stool examinations have yielded negative results. To obtain mucosal exudate, a glass or metal pipette must be used, because amebas adhere to cotton swabs. Microscopy cannot distinguish *Entamoeba histolytica* from the nonpathogenic *E. dispar*. The presence of amebas on stool microscopy in an asymptomatic patient should suggest the presence of nonpathogenic *E. dispar*; treatment is not indicated.

The diagnosis of amebiasis has been greatly improved by the development of stool antigen assays. Monoclonal antibody–based enzyme immunoassay for *E. histolytica* antigens has a sensitivity and specificity of approximately 95% and can distinguish *E. histolytica* from *E. dispar*. PCR techniques also have been developed but are not clinically available.

Serologic tests are quite sensitive and specific for active amebic infection. Because administration of steroids to patients with amebic colitis is potentially fatal, and because identification of the parasite in stools is difficult, a serologic test for amebiasis should be done in all newly diagnosed cases of inflammatory bowel disease before initiation of steroid therapy.

**Differential Considerations.** Amebiasis should always be considered in cases of acute dysentery-like colitis and in the differential diagnosis for any chronic diarrhea, especially when the stool contains blood-streaked mucus. Amebiasis also should be suspected in homosexual men with acute or chronic colitis. Among patients with AIDS, however, amebic dysentery is rare. Patients with nondonysenteric amebiasis often are misdiagnosed as having irritable bowel syndrome, diverticulitis, or regional enteritis.

**Management.** Substantial controversy previously existed over whether asymptomatic cyst passers should be treated. Today, however, advances in testing permit distinction between nonpathogenic *E. dispar* and *E. histolytica*, so an accurate diagnosis is now possible. Accordingly, it seems prudent to treat for *E. histolytica* infection in all patients in whom this organism is detected, even asymptomatic carriers. If only *E. dispar* is identified, treatment is unnecessary. When differentiation is not possible and the patient is asymptomatic, treatment is not recommended unless the clinical picture suggests an increased likelihood of *E. histolytica* infection. Such would be the case with patients with high specific antibody titers, a history of close contact with a patient with invasive amebiasis, or a patient with symptoms during an outbreak of amebiasis. In symptomatic patients who are diagnosed with *E. histolytica* or *E. dispar* infection, other pathogens should be ruled out before *E. histolytica* can be assumed to be the cause.

For treatment of benign cyst passers, paromycin (aminosidine) 500 mg orally three times a day for 7 days should be effective. Other regimens include oral iodoquinol, 650 mg orally three times a day for 20 days, and diloxanide furoate, 500 mg orally three times a day for 10 days. For mild to moderate intestinal infection, metronidazole is added (see Table 92-2). Treatment with metronidazole should precede treat-
Enterobiasis

Epidemiology. Enterobius vermicularis, also known as pinworm or seatworm, is perhaps the most prevalent parasite in the United States. It is estimated that 20 to 30% of all children are infected with pinworms; 200 million people are infected annually worldwide, 40 million in the United States alone. Adult worms are small, spindle-shaped, white to yellowish roundworms that live in the cecum and adjacent portions of the large and small bowel. The female averages 10 mm in length, and the male is 3 mm long. The gravid female migrates through the anal canal at night and oviposits her eggs (up to 50,000) onto the perineal area. The eggs become infective larvae 4 to 6 hours after deposition. Once ingested, the eggs hatch in the duodenum, and the larvae mature as they migrate down to the cecum. Approximately 1 month from the time of ingestion, newly developed, gravid females are again discharging eggs.57 The human body is the only natural host of E. vermicularis. The most common means of infection, particularly in children, is by the direct transfer of eggs from the anus to the mouth on contaminated fingers. Retrograde infection, seen primarily in adults, may sometimes occur. In such cases, larvae hatch in the perineal region, reenter the anus, and migrate to the cecum. Spread within family and children’s groups occurs readily, either by direct transfer of eggs or by airborne transmission. The eggs, which are relatively resistant to desiccation, also contaminate night clothes and bed linens, where they remain viable and infective for 2 to 3 weeks.

Pathophysiology. Because E. vermicularis does not penetrate the mucosa, no specific anatomic lesions are initially seen. The movement of the worms or the presence of the eggs on the perineum usually causes local tingling or itching. Scratching causes irritation of the skin, which can lead to excoriations, eczematous dermatitis, and secondary bacterial infections. In women, gravid female worms can migrate through the vagina and uterus into the fallopian tubes, where they may evoke vaginitis, endometritis, or salpingitis. Young girls with pinworms; 200 million people are infected annually worldwide. The ease of airborne dissemination of the eggs, their resistance to desiccation, and the poor hygienic practices of children all increase the likelihood of reinfection. Ova also are resistant to ordinary fumigants and disinfectants, making control in schools, institutions, and the home very difficult.

Clinical Presentation. The most common symptom is pruritus ani. This usually occurs at night in relation to the nocturnal migration and oviposition. Scratching may lead to secondary skin changes and bacterial infection. Restlessness, insomnia, and enuresis probably are a result of the pruritus. Alternative presentations include abdominal pain, rectal bleeding, diarrhea, and weight loss. In the absence of host autoinfection, infection typically lasts 4 to 6 weeks.

Diagnostic Strategies. Adult worms may be recognized in the perineal area, and in suspected cases, nocturnal examination of this area using a flashlight may confirm infection. Worms sometimes can be seen on the surface of stool as well. The most reliable way to diagnose infection is to examine material taken from the perineal area for ova. The cellophane tape test is simple and reliable. The tape is folded, sticky side out, over the end of a tongue blade, pressed firmly against the perineal area, and then spread on a glass slide with toluene and examined under the low-power objective lens of a microscope. The typical eggs are identified easily.

A single cellophane tape test will detect approximately 50% of infections. If done daily for 3 days, the test will detect 90% of infections; after 5 days, it will detect 99%. Examining stool specimens for ova is rarely helpful; only 5% of patients will have eggs in the stool. Scrapings from under the fingernails may reveal the ova.57 Eosinophilia is not found because the worm does not have a tissue phase.

Management. All infected persons in a family or communal group should be treated simultaneously. It is accepted practice to treat empirically all other members of the same group at the same time, even if they are not infected. The drugs of choice are albendazole, 400 mg by mouth once; mebendazole (Vermox), in a single oral dose of 100 mg chewed well; and pyrantel pamoate (Antiminth), in a single oral dose of 11 mg/kg (maximum dose, 1 g). With all of these treatments, a second dose should be administered 2 weeks later. The repeat dose is needed because mature worms seem to be more vulnerable than young worms. Although the maturation process takes 1 to 2 months, a second dose is effective in eradicating the organism in all stages of the life cycle in 90 to 95% of infections.57

The ease of airborne dissemination of the eggs, their resistance to desiccation, and the poor hygienic practices of children all increase the likelihood of reinfection. Ova also are resistant to ordinary fumigants and disinfectants, making control in schools, institutions, and the home very difficult.

Diarrhea in Patients with AIDS

Epidemiology. Diarrhea is the most common manifestation of gastrointestinal disease in patients with AIDS and may be the presenting symptom or a life-threatening complication of the disease. The occurrence rate is greater than 90% in developing countries and historically 50 to 60% in the United States. With the widespread use of HAART, the incidence of infectious

*Formerly Salmonella typhimurium.

AIDS, acquired immunodeficiency syndrome.
diarrhea has decreased dramatically in the United States and other developed countries, even among those with CD4+ counts less than 200/mm³. It is believed that most cases of diarrhea in patients with AIDS in developed countries are now noninfectious in nature, most often related to the use of protease inhibitors; hence, the clinician should ask about recent changes in the HAART regimen in addition to considering infectious causes.46,55

Worldwide, patients who are HIV-positive and those with active AIDS are more susceptible to infection both from the usual enteric organisms and from opportunistic organisms. Diarrheal diseases are much more problematic in patients with AIDS because of their diminished immunity and underlying poor nutritional status.50 A vastly expanded profile of pathogens may potentially cause diarrhea in patients with AIDS compared with immunocompetent persons. Also, the ramifications of the disease are significantly more serious, necessitating a much more aggressive diagnostic evaluation and treatment regimen.

Pathophysiology. The early concept of mucosal transmission of HIV was that it occurred through mucosal trauma that created breaches in the physical barrier of the genital or rectal epithelium, allowing introduction of viral particles directly to the bloodstream. It is now known that infection also occurs after intramuscular inoculation of mucous membranes. With gastrointestinal exposure, virions of certain HIV strains bind to particulate-sampling M cells (membranous epithelial cells) in the gastrointestinal mucosa and undergo receptor-mediated transport from intestinal lumen to lamina propria, with subsequent infection of CD4+ lymphocytes located in the gastrointestinal mucosa. Mucosal biopsy specimens in up to 40% of patients with AIDS demonstrate HIV virions, with depletion of CD4+ lymphocytes in the lamina propria and apoptosis of both HIV-infected and non–HIV-infected lymphocytes. It also has been observed that in a significant number of HIV-infected patients, diarrhea develops in the absence of an identifiable gastrointestinal pathogen, and that this pathogen-negative HIV-related diarrhea subsides with institution of HAART. These findings suggest that HIV itself can induce a primary enteropathy, although specific mechanisms have yet to be elucidated.61

In the population of homosexual men, unprotected receptive anal intercourse and anal-oral contact among multiple partners provide exposure to a diverse spectrum of enteric pathogens. In the heterosexual intravenous drug-abusing population, infection spreads primarily by water- and foodborne transmission of the organisms. Patients with AIDS are unable to combat these intestinal pathogens, probably because of a combination of T lymphocyte functional deficiency and underlying HIV-induced enteropathy.

Etiology. A known enteric pathogen can be identified in approximately 85% of patients with AIDS who are experiencing diarrhea. Multiple pathogens may be present in as many as 20 to 25% of patients. Homosexual men with AIDS experience diarrhea more often than do other patients with AIDS. Diarrhea also develops more often in patients who do not have access to or are not compliant with HAART and in those infected with resistant strains of HIV than in other AIDS patients.62

Cryptosporidium and cytomegalovirus infections are the two most common causes. The incidence of each is approximately 20%.52,63 Chronic high-volume watery diarrhea most often is from one of the coccidia Cryptosporidium and Isospora belli. Although self-limited in the healthy host, coccidial disease often is persistent in patients with CD4+ counts less than 200/mm³. Cytomegalovirus and Mycobacterium avium-intracellulare also produce a chronic illness in those with CD4+ counts less than 100/mm³. Fever, weight loss, and abdominal pain are prominent; diarrhea is mild to moderate. Many patients die within 6 months of diagnosis. Microsporidia have emerged as a common cause of diarrhea in patients with AIDS in whom CD4+ counts are less than 100/mm³. Worldwide, these organisms have been identified in 10 to 20% of patients with AIDS who are experiencing diarrhea. In one prospective study in the United States, microsporidia were identified in 39% of patients with AIDS undergoing small bowel biopsy for evaluation of diarrhea.63

Salmonella infections, especially with S. Typhimurium, are common in immunocompromised hosts.66 Patients with AIDS who acquire Salmonella enteritis are at increased risk for bacteremia and metastatic focal infection compared with normal hosts. Clostridium difficile enteritis occurs more commonly in patients with AIDS owing to the common use of prophylactic antibiotic therapy and frequent hospitalizations. It is the most common bacterial enteritis in the AIDS population. Clinical presentation, response rate, and relapse rate are different from those in the healthy host.63 Giardiasis occurs with a frequency and severity that are unrelated to the degree of immune compromise.55

Entamoeba histolytica infection is neither more prevalent nor more severe in HIV-infected patients. When amebae are present, it is rare for these organisms to cause invasive disease in patients with AIDS.63 For unknown reasons, Yersinia, V. parahaemolyticus, viruses (non-cytomegalovirus), Neisseria gonorrhoeae, and Chlamydia trachomatis are relatively unusual causes of diarrhea in patients with AIDS. Shigellosis and campylobacteriosis are more common among male patients with AIDS who have sex with men than among HIV-negative men who have sex with men.

Clinical Presentation. In patients with AIDS, diarrhea presents in one of three ways. First, at the time of HIV seroconversion, patients usually experience diarrhea, nausea, anorexia, and malaise in association with an acute infectious mononucleosis–like syndrome. Second, diarrhea may be the presenting symptom of full-blown AIDS, with associated fever, malaise, anorexia, and significant weight loss. The most common presentation, however, is for diarrhea to start well after AIDS has become clinically apparent and when the CD4+ count falls below 300/mm³. In these cases, the patient typically has a chronic debilitating infection that rarely remits spontaneously unless CD4+ counts are normalized using HAART. Diarrhea often is accompanied by profound weight loss, major nutritional impairments, and a diminished sense of well-being. Many cases are refractory to antimicrobial treatment and persist until death, or may even be the cause of death.55,63

In patients with AIDS, the presenting signs and symptoms generally do not allow consistent classification of diarrheas, as is done for the immunocompetent host. This is so in part because many patients with AIDS have multiple, concomitant enteric pathogens. However, some clinical pictures are typical. Patients with a fulminating clinical course usually have a disseminated infection, such as infection with cytomegalovirus or M. avium-complex. Massive weight loss also is associated with diarrhea due to infection with those two organisms and the coccidia Cryptosporidium and Isospora. Voluminous, watery diarrhea usually is due to one of the coccidial organisms. Patients with a proctocolitis-like picture most often have herpes simplex virus or cytomegalovirus infection. Strongyloides should be considered in any immunocompromised patient who experiences sudden clinical deterioration with eosinophilia, polymicrobial sepsis, meningitis, or adynamic ileus.65

Complications. The most common complications are dehydration, electrolyte abnormalities, and malnutrition resulting from
both fluid loss and malabsorption. Cytomegalovirus infection can produce gastrointestinal hemorrhage or perforation or toxic megacolon. *M. avium-complex* infection often manifests with severe anemia, weight loss, and a rapid downhill course of persistent weakness, malaise, and malabsorption. Bacteremia historically was found in as many as 40 to 45% of patients with AIDS and diarrhea, usually caused by *M. avium-complex* or *Salmonella* species. The incidence has decreased markedly over the past decade as the use of HAART has increased.63

**Diagnostic Strategies.** The diagnostic approach to patients with AIDS who are experiencing diarrhea is entirely different from that to an immunocompetent host. In 80 to 90% of cases, one or more enteric pathogens are found; of the pathogens identified, a majority are susceptible to appropriate antimicrobials.55,62 Diarrhea in patients with AIDS in whom CD4 counts are less than 300/mm³ generally is not self-limited and requires medical intervention to effect resolution. Therefore, each patient merits a diagnostic evaluation (Box 92-2). Infectious causes are detected less frequently in patients being treated with HAART.62

Patients with AIDS who are experiencing diarrhea should have up to three stool specimens cultured for enteric bacteria, because fecal shedding of pathogenic bacteria can be intermittent. Stool should also be examined for parasites, using antigen detection assays where available or microscopy of multiple samples for ova, parasites, and mycobacteria. The usual bacterial enteric pathogens are readily identified, but the protozoal infections can be difficult to detect if microscopy-based strategies are used. In patients with severe diarrhea from *Cryptosporidium*, the first stool examination usually yields a positive result, but in less severe cases, additional samples may have to be studied to make the diagnosis. Specialized techniques are necessary to detect most of the viral agents.

Blood cultures are a valuable diagnostic adjunct. Bacteremia may be found in up to 43% of patients, and a blood culture may yield a positive result when the stool cultures and examinations fail to reveal a pathogen.64 The most common organisms detected by means of blood culture are *M. avium-complex*, cytomegalovirus, *Salmonella*, and occasionally herpes simplex virus. Most cases of *M. avium-complex* bacteremia occur in heterosexual intravenous drug abusers. A routine complete blood cell count demonstrating eosinophilia suggests parasitic infection with *Strongyloides stercoralis* or *Isospora*.65

If results of these diagnostic tests are negative, endoscopy should be performed to obtain mucosal biopsy samples from affected areas of the rectum or colon. Rectal biopsy, which can be performed easily even in seriously ill patients, is an indispensable tool in the diagnosis of cytomegalovirus infection. Viral inclusion bodies with clear halos typical of cytomegalovirus can be demonstrated or cytomegalovirus DNA can be detected using PCR techniques. Special staining examinations, DNA detection techniques, or culture of the biopsy tissue also may diagnose *M. avium-complex*, *Cryptosporidium*, or *Giardia* infections that were missed on stool examination. Herpes simplex virus infection can be identified microscopically by detecting multinucleated giant cells or cultures obtained at the time of endoscopy.

Small bowel biopsy and duodenal aspiration are indicated when stool examination, cultures, and sigmoidoscopy fail to yield a definitive diagnosis. Small bowel studies are most helpful for detecting infection due to *Cryptosporidium*, cytomegalovirus, *M. avium-complex*, *Giardia*, or *I. belli*.65

**Differential Considerations.** Kaposi’s sarcoma, even if it involves the bowel, rarely produces diarrhea. Symptomatic oral and esophageal candidiasis is common in patients with AIDS, but diarrhea from *Candida* has not been reported. Diarrhea can be a side effect of antiretroviral drugs used to treat AIDS, especially the protease inhibitors nelfinavir and the combination agent lopinavir plus ritonavir.

Antibiotic-associated colitis from *C. difficile* should be considered when onset of the diarrhea follows antibacterial therapy or hospitalization. Ulcerative colitis can mimic or be mimicked by cytomegalovirus colitis.62 Aphthous ulceration, particularly of the colon, should be considered when cultures and endoscopy biopsy specimens fail to reveal evidence of infection with common infectious pathogens, herpes simplex virus, or cytomegalovirus. Empirical corticosteroid therapy may lead to dramatic improvement in these patients.63 Acute proctitis should be differentiated from diarrhea or acute colitis because the investigative evaluation and treatment regimens are distinctly different.

**Management.** The best strategy for treatment and prevention of acute and chronic infectious diarrhea is maintenance of CD4+ counts through HAART. Treatment of diarrhea in patients with AIDS also includes diet, antimitoty agents, and antimicrobial agents. Diets that are lactose-free and low in fat often diminish the diarrhea caused by malabsorption. Patients should avoid intestinal stimulants such as caffeine, raw or inadequately cooked seafood, rattlesnake preparations, and untreated water. Variable success has been reported with standard antimitoty agents such as diphenoxylate or loperamide. In patients with cryptosporidiosis, these agents commonly cause a marked increase in crampy abdominal pain; long-acting

---

**BOX 92-2**

**DIAGNOSTIC PROTOCOL FOR EVALUATING DIARRHEA IN PATIENTS WITH AIDS**

### Initial Evaluation

Indicated in all patients.

1. Stool cultures for enteric bacteria—*Salmonella*, *Shigella*, *Campylobacter*, *Yersinia*, STEC
2. Stool examination for *Giardia*, *Cryptosporidium*, *Isospora*, *Cyclospora*, amebas, and mycobacteria; *Clostridium difficile* toxin assay
3. Blood cultures
4. Proctosigmoidoscopy in patients with clinically severe colitis or a proctocolitis picture, especially homosexual men

### Further Evaluation

Indicated if initial study results are negative or to look for multiple organisms present if a patient fails to respond to appropriate therapy for an identified pathogen.

1. Repeat stool cultures and examinations, possibly add culture for viruses
2. Colonoscopy or esophagogastroduodenoscopy performed to obtain duodenal fluid and small bowel and colonic biopsies, which are examined for:
   a. Duodenal fluid examination for ova and parasites
   b. Duodenal and colonic biopsy specimens cultured for mycobacteria, cytomegalovirus, and herpes simplex virus; colonic biopsy tissue also is cultured for bacterial enteric pathogens (add testing for gonorrhea and chlamydial infection in patients with acute proctitis)
   c. Biopsy specimens examined using multiple stains (e.g., acid-fast, hematoxylin-eosin, Giemsa, silver, periodic acid–Schiff) for protozoa, mycobacteria, and cells containing viral inclusion bodies

STEC, Shiga toxin–producing *Escherichia coli.*
morphine sulfate derivatives have provided better clinical relief.46 Specific antimicrobial therapy can lead to marked symptomatic improvement in 55 to 75% of patients in whom a pathogen has been identified (Table 92-6). Many patients show substantial improvement after therapy, even when the organism has not been eliminated or the diarrhea persists. Antimicrobial therapy should be dictated by the results of the diagnostic evaluation. Empirical use of antimicrobial agents is not indicated; no one antimicrobial agent can possibly provide reasonable coverage for the wide variety of causative organisms found in these patients. The possibility of infection by multiple organisms must always be considered, especially when patients do not respond to antimicrobial agents known to be effective against an identified pathogen.

Ganciclovir, a nucleoside analogue similar to acyclovir, is effective in inducing clinical remission in up to 90% of patients with gastrointestinal cytomegalovirus infection.66 Foscarnet is also effective and typically is used in ganciclovir-resistant infections. The dosage of both drugs should be reduced in patients with low creatinine clearance. Treatment for the other most common cause of diarrhea in patients with AIDS, cryptosporidiosis, has improved with the use of nitazoxanide: in one study of HIV-positive patients with CD4+ counts greater than 50/mm3, 90% responded to a dose of 2 g/day, compared with 20% of those who received placebo.46 Infection with L. belli and C. cayetanensis can be cured with TMP-SMX.3 M. avium-complex infection is poorly responsive to therapy, and death generally ensues within 6 to 8 months of diagnosis. Virtually all of the other organisms listed in Table 92-5 are susceptible to the usual therapeutic agents, although higher dosages and longer courses of treatment often are required. Recurrences of diarrhea due to either the opportunistic organisms or the usual enteric organisms are common. Chronic suppressive antimicrobial therapy may be indicated to prevent relapse or reinfection.3

TRAVELER’S DIARRHEA

Epidemiology. It is said that “travel expands the mind and loosens the bowels.” Diarrhea is by far the most common health problem among the 12 million people who travel from an industrialized nation to a developing country each year. Travel to high-risk areas is associated with diarrheal attack rates of 30 to 50%. Among travelers to industrialized countries, however, the development of diarrhea is infrequent. For visitors to the United States, the attack rate is less than 4%.55

Traveler’s diarrhea is more common in young adults than in elderly persons. Travelers with inflammatory bowel disease, diabetes, or immune compromise and those taking antacids also are at increased risk.67

Pathophysiology. The syndrome is caused by an infection acquired by ingesting fecally contaminated food or water. High-risk items include raw leafy vegetables, raw or undercooked meats or seafood, unpeeled fruits, unpasteurized dairy products, tap water, and ice. Once an organism is ingested, rapid and dramatic change occurs in the traveler’s intestinal flora. When the ingested inoculum overcomes host defense mechanisms, diarrhea develops. Most often, the pathomechanism involves elaboration of enterotoxins that produce a secretory diarrhea. When organisms are invasive, rather than toxigenic, a typical infectious enteritis results.

Etiology. Pathogens that commonly cause traveler’s diarrhea are listed in Table 92-7. Bacterial enteropathogens cause approximately 80% of cases of traveler’s diarrhea. Enterotoxinogenic E. coli is the most common pathogen and can be acquired anywhere in the world, although the incidence of infection is higher in Latin America than in Africa, Asia, or the Middle East. V. parahaemolyticus is an increasingly common cause because of its association with consumption of raw or inadequately cooked seafood. The organism commonly causes diarrhea in persons traveling to Japan or Asia or in those vacationing on cruise ships.15,53,68

Plesiomonas shigelloides typically is associated with uncooked shellfish, especially oysters. It also is associated with travel to Mexico. Plesiomonas produces a typical invasive enteritis.15 E. coli O157:H7 and enteroinvasive E. coli each cause up to 5% of cases of traveler’s diarrhea.68 Another type of E. coli, enteropathogenic E. coli, may be the cause of a significant number of the previously undiagnosed cases of traveler’s diarrhea. Viral agents cause up to 10% of cases of traveler’s diarrhea.68 Parasitic pathogens are implicated in approximately 10% of cases of traveler’s diarrhea. Giardia is the most common parasite acquired by travelers; travelers to the former Soviet Union, particularly Leningrad and Moscow, have a very high risk for acquiring giardiasis. Entamoeba histolytica, Cyclospora, and Cryptosporidium are each implicated in less than 2% of cases.68,69

Clinical Presentation. Traveler’s diarrhea typically begins abruptly, with production of four or five loose or watery stools per day for 1 to 3 days. Approximately one third of patients are temporarily confined to bed, and the symptoms last more than a week in 10% of patients.69 Onset usually is within the first 3 to 4 days of travel but can occur at any time, including after the patient arrives home. Patients may not associate their diarrhea with recent travel because the incubation time for the infection, particularly if it is parasitic, may have been long enough to allow them to return home before the symptoms began. Associated symptoms include abdominal cramps, nausea, bloating, urgency, and occasionally vomiting, fever, chills, headache, malaise, tenesmus, and bloody stools. Symptoms and signs depend on whether the pathogen is noninvasive or invasive. Traveler’s diarrhea may ruin a trip, but it is rarely life-threatening.

Prevention.

Diet. Traditionally, instruction regarding food and beverage preparation has been touted to prevent traveler’s diarrhea. Most travelers, however, do not follow such advice. Ideally, tourists should eat only foods that are freshly prepared and served piping hot. High-risk foods should be assiduously avoided, and travelers should follow the Peace Corps adage of “boil it, cook it, peel it, or forget it.” Thirsty travelers should be advised to avoid ice and to drink beverages such as tea and coffee that are made with boiled water, canned or bottled carbonated beverages, and wine.67,68 Boiling water is by far the most reliable method to make it safe for drinking and brushing teeth. Travelers and outdoor enthusiasts should be advised to bring the water to a vigorous boil and allow it to cool without adding ice. Boiling destroys virtually all bacteria, viruses, and parasitic cysts. A pinch of salt in each quart improves the taste. When boiling is not feasible, water can be chemically disinfected with 2% tincture of iodine drops or tetracycline hydroiodide tablets, such as Globarine or Potable Aqua, available from pharmacies and sporting goods stores.

Nonantimicrobial Medications. The nonantimicrobial agent most studied in the prevention of traveler’s diarrhea is bismuth subsalicylate (e.g., Pepto-Bismol). Taking two tablets, or 2 ounces, four times per day decreases the incidence of traveler’s diarrhea by 65%. This dosage, however, contains the daily equivalent of eight 5-grain aspirin tablets. Bismuth subsalicylate should not be used in patients who are allergic to salicylates, those taking large doses of salicylates for arthritis, or

TRAVELER’S DIARRHEA

Epidemiology. It is said that “travel expands the mind and loosens the bowels.” Diarrhea is by far the most common health problem among the 12 million people who travel from an industrialized nation to a developing country each year. Travel to high-risk areas is associated with diarrheal attack rates of 30 to 50%. Among travelers to industrialized countries, however, the development of diarrhea is infrequent. For visitors to the United States, the attack rate is less than 4%.55

Traveler’s diarrhea is more common in young adults than in elderly persons. Travelers with inflammatory bowel disease, diabetes, or immune compromise and those taking antacids also are at increased risk.67

Prevention.

Diet. Traditionally, instruction regarding food and beverage preparation has been touted to prevent traveler’s diarrhea. Most travelers, however, do not follow such advice. Ideally, tourists should eat only foods that are freshly prepared and served piping hot. High-risk foods should be assiduously avoided, and travelers should follow the Peace Corps adage of “boil it, cook it, peel it, or forget it.” Thirsty travelers should be advised to avoid ice and to drink beverages such as tea and coffee that are made with boiled water, canned or bottled carbonated beverages, and wine.67,68 Boiling water is by far the most reliable method to make it safe for drinking and brushing teeth. Travelers and outdoor enthusiasts should be advised to bring the water to a vigorous boil and allow it to cool without adding ice. Boiling destroys virtually all bacteria, viruses, and parasitic cysts. A pinch of salt in each quart improves the taste. When boiling is not feasible, water can be chemically disinfected with 2% tincture of iodine drops or tetracycline hydroiodide tablets, such as Globarine or Potable Aqua, available from pharmacies and sporting goods stores.

Nonantimicrobial Medications. The nonantimicrobial agent most studied in the prevention of traveler’s diarrhea is bismuth subsalicylate (e.g., Pepto-Bismol). Taking two tablets, or 2 ounces, four times per day decreases the incidence of traveler’s diarrhea by 65%. This dosage, however, contains the daily equivalent of eight 5-grain aspirin tablets. Bismuth subsalicylate should not be used in patients who are allergic to salicylates, those taking large doses of salicylates for arthritis, or

patients taking oral anticoagulants, uricosuric drugs, or methotrexate. Salicylates have antiplatelet effects, inhibit the activity of uricosuric drugs, and increase the toxicity of methotrexate by decreasing its renal clearance. Bismuth subsalicylate also turns the tongue and stool black and may cause mild tinnitus and interfere with the bioavailability of doxycycline.

Antiperistaltic agents such as diphenoxylate and loperamide are not effective prophylactic agents. Controlled studies have indicated that the prophylactic use of diphenoxylate actually increases the incidence of traveler’s diarrhea: slowing of the gut allows more time for organisms to colonize and elaborate toxin or produce infection.

*Rough estimates, which vary depending on locales visited.

In addition, if the traveler is provided with a prescription for a suitable antibiotic based on regional resistance patterns, taking one dose in combination with loperamide immediately after the onset of diarrhea often will halt symptoms within hours. For these reasons, prophylactic use of antibiotics before the onset of symptoms is no longer recommended, except in cases of significant concurrent illness or immunocompromised status.  

If prophylaxis is indicated, a single daily dose of prophylactic antibiotics such as ciprofloxacin (500 mg), norfloxacin (400 mg), or rifamixin (200 mg), in combination with bismuth subsalicylate two tablets (262 mg/tablet) or 30 mL four times daily can effectively prevent traveler’s diarrhea in up to 90% of persons. The regimen is started on the day before travel and continued until 2 days after returning home. TMP-SMX also can be used but is not recommended as a first-line agent because of significant resistance.

**Management.**

**Diet.** In most patients, fluid and electrolyte balances can be maintained by drinking potable fruit juices, bottled beverages, or caffeine-free soft drinks.

**Nonantimicrobial Medications.** Adsorbents such as kaolin or pectin are ineffective for treating traveler’s diarrhea. They may give the stools more consistency but have not been shown to decrease cramping or the frequency of stooling, or to shorten the course of an infectious diarrheal illness. Nonantimicrobial agents such as bismuth subsalicylate, paregoric, codeine, diphenoxylate, or loperamide may provide prompt but temporary symptomatic relief.

Loperamide (initial dose 4 mg followed by 2 mg after each unformed stool for 2 days; total dosage no more than eight 2-mg capsules/day) has been shown to provide significantly more relief than that obtained with bismuth subsalicylate (30 mL orally every 30 minutes for 3 to 5 hours on each of 2 days, for a total dose of 240 mL/day).  

**Antimicrobials.** Antibiotic therapy can provide prompt relief of symptoms, decrease the rate of stooling, and shorten a typically 1- to 3-day illness to a few hours. In cases of mild toxigenic, nondysenteric traveler’s diarrhea, a single dose of ciprofloxacin 750 mg PO in combination with loperamide often resolves the symptoms within an hour. When the course is extended to 3 days, response rates of up to 98% are attained. In patients with high fever, bloody stools, or the typical bacterial or invasive picture, the treatment of choice is norfloxacin, 400 mg twice daily, or ciprofloxacin, 500 mg twice daily, in combination with loperamide. The duration of treatment generally is 3 days, although one double dose may be all that is necessary.  

Persons with dysentery who fail to respond to one antibiotic should promptly be switched to another. Azithromycin may be effective in cases in which fluoroquinolones either cannot be used or are ineffective. The quinolone agents are not recommended for use in children and pregnant women.

The antibiotic rifamixin was FDA-approved in 2004 for the treatment of traveler’s diarrhea in adults and children older than 12 years of age. It is a nonabsorbable antibiotic that acts by inhibiting RNA synthesis, and the potential for development of bacterial resistance to this agent is believed to be low. Several studies demonstrate that oral rifamixin 200 mg three times daily for 3 days is an effective treatment for traveler’s diarrhea.

A summary of current recommendations for the prevention and treatment of traveler’s diarrhea is outlined in Box 92-3. Further detailed information on traveler’s diarrhea and the other medical problems of travelers can be found at the Center for Preventive Services section of the CDC’s website, [http://wwwnc.cdc.gov/travel/default.aspx](http://wwwnc.cdc.gov/travel/default.aspx). The CDC’s “Yellow Book,” *Health Information for International Travel,* can be downloaded for free at [http://wwwnc.cdc.gov/travel/contentYellowBook.aspx](http://wwwnc.cdc.gov/travel/contentYellowBook.aspx), and the CDC provides up-to-the-minute travel information through its traveler’s hotline telephone number, 877-FYI-TRIP.
BOX 92-3  CURRENT RECOMMENDATIONS FOR THE PREVENTION AND TREATMENT OF TRAVELER’S DIARRHEA

1. Provide instruction regarding sensible dietary practices and drinking water management.
2. Reserve prophylaxis for patients with special circumstances, including severe concurrent illness or immunosuppression. The basis of this recommendation is threefold: first, the potential for aspirin-related complications; second, the ramifications of widespread use of prophylactic antibiotics in terms of adverse medication reactions or the emergence of resistant organisms; and third, the availability of highly successful treatment strategies.
3. Other patients who request prophylaxis should be steered toward the use of bismuth subsalicylate rather than antibiotics.
4. For those requiring prophylaxis, one of the quinolones—norfloxacin, ciprofloxacin, or rifamixin—is recommended.
5. For all patients requiring prophylaxis, it is reasonable to institute prompt antimicrobial therapy once traveler’s diarrhea occurs.
   a. Toxigenic/nondysentery: loperamide combined with one dose of ciprofloxacin 750 mg orally.
   b. Infectious/dysentery: norfloxacin, ciprofloxacin, or rifamixin—alone or in combination with loperamide twice daily for 3 days.
   c. The rare traveler with persistent symptoms, particularly fever, chills, or blood or mucus in stools, unresponsive to antimicrobial therapy within 24 to 48 hours, should seek immediate medical attention.

KEY CONCEPTS

- Contact isolation precautions should be followed for all patients with significant diarrhea that continues during the ED stay.
- Most otherwise healthy patients presenting with diarrhea do not require laboratory testing or antibiotic therapy.
- Fecal testing should be reserved for those patients who are systemically ill, are febrile, have significant comorbid disease, have bloody stools, or report recent antibiotic use, or in whom exposure to a treatable or reportable pathogen is strongly suspected.
- Empirical treatment of diarrhea in adults with a fluoroquinolone or TMP-SMX generally is not recommended but is acceptable for traveler’s diarrhea and when severe inflammatory diarrhea is present with a low risk of E. coli O157:H7 as its cause. This indication includes bloody diarrhea in patients with a temperature greater than 38.5°C. “False-positive” blood in stools may come from aggravation of hemorrhoids or perianal irritation secondary to copious stooling. Fecal leukocytes or lactoferrin testing may help distinguish inflammatory diarrhea from that of other causes but has low specificity. Stool testing should be performed before institution of all empirical treatment.
- Milk and other lactose-containing foods should be avoided because gastroenteritis often leads to transient lactose intolerance. Caffeine products also may worsen diarrhea. Bowel rest is not necessary or advantageous, however, and patients should be encouraged to eat and drink what they find palatable during the illness.
- Risks of empirical antibiotic treatment include adverse and allergic reactions, possible increase in the risk of hemolytic uremic syndrome in the case of E. coli O157:H7 infection, prolonged shedding of salmonellae of non-Typhi serotypes, and increased organism resistance.
- Treatment should be considered in patients who are still significantly ill when culture results are reported, particularly if they are immunocompromised or have a significant underlying medical illness, or in cases in which the fecal shedding could represent a public health hazard.
- Patients with sickle cell anemia, other hemolytic anemias, or AIDS are unusually susceptible to Salmonella bacteremia.
- Although risk associated with antimotility agents may be overstated, these agents are still not recommended for treatment of invasive enteritis unless antibiotics also are used.
- In patients with Y. enterocolitica gastroenteritis, the abdominal pain and diarrhea usually persist for 10 to 14 days or longer; in a substantial number of patients with yersiniosis, in particular adolescents and young adults, an ileoceccitis may develop. In these cases, lower abdominal pain with little or no diarrhea predominates and may perfectly mimic the pain of acute appendicitis.
- The symptoms of scombroid fish poisoning, which resemble those in histamine intoxication and usually develop abruptly within 20 to 30 minutes of eating the fish, consist of facial flushing, diarrhea, severe, throbbing headache, palpitations, and abdominal cramps, and generally last less than 6 hours. The mainstay of therapy is antihistamine administration.
- Many cases of C. difficile antibiotic–associated enterocolitis are self-limited, provided that the offending agent is discontinued. When stopping the antibiotic does not resolve the diarrhea, or when the diarrhea is severe, empirical antibiotic treatment should be started promptly. Either oral metronidazole or oral vancomycin can be used to eradicate C. difficile colitis.
- Giardia is the most common cause of water-borne diarrheal outbreaks in the United States. Most patients harboring Giardia organisms are asymptomatic. The most common symptoms of acute infection are abdominal distention, colicky pain with audible borborygmi, flatulence, and frequent stools. All patients
with proven *Giardia* infection should receive treatment even if they are asymptomatic.  
- Diarrhea is the most common manifestation of gastrointestinal disease in patients with AIDS and may be either the presenting symptom or a life-threatening complication of the disease. Diarrhea in patients with AIDS in whom CD4⁺ counts are less than 300/mm³ generally is not self-limiting but requires medical intervention to effect resolution. Therefore, each patient deserves a diagnostic evaluation.  
- ETEC is responsible for 40 to 50% of all cases of traveler’s diarrhea, and these organisms can be acquired anywhere in the world. Prophylactic antibiotics are no longer recommended for otherwise healthy patients, but quick resolution of diarrhea is possible with prompt treatment.

IRRITABLE BOWEL SYNDROME

Perspective

Irritable bowel syndrome (IBS) is a chronic non–life-threatening disorder characterized by abdominal pain and alteration in bowel habits. IBS is an extremely common disorder; estimates put the prevalence in the North American population at 10 to 15%, with women affected twice as often as men. Although only one third of patients who have the clinical syndrome ever seek medical attention, IBS accounts for more than 10% of all visits to primary care physicians and more than 25% of all visits to gastroenterologists. IBS is said to contribute more impairment to quality of life than does either diabetes or renal failure.

No specific physical or laboratory abnormalities defining IBS have been identified. IBS is a functional asomatic syndrome that is defined by criteria and usually is diagnosed after other, more serious diagnoses are excluded. A new diagnosis of IBS may be difficult to make in the emergency department (ED) because many of the studies required to exclude other conditions are not readily available. Initially, patients usually are discharged with a diagnosis of “abdominal pain of unclear etiology” or the equivalent. Such patients and even patients with known IBS presenting with acute symptoms pose a diagnostic challenge. Symptoms of IBS overlap with those of other conditions, including some that are life-threatening, which must be excluded before hospital discharge.

Principles of Disease

Although the cause of IBS is unknown, it is associated with several pathophysiologic findings suggesting that it is a disorder of altered gut motility, gut sensation, and perception of intestinal activity. IBS initially was thought to be primarily a psychiatric disorder because there are no visible anatomic abnormalities, and because stress is an exacerbating factor. Physiologic testing has since shown that patients with IBS have disturbances in the rhythmic pattern of electrical activity in the intestine and in how the intestine responds to stimulation. Patients with IBS seem to be more attuned to activity in the abdomen as well, sensing different phases of intestinal motor activity and intestinal content movement more than people without IBS.

Psychiatric conditions often coexist with IBS, ranging from generalized anxiety disorder to major depression. An association with previous sexual abuse also has been reported. In women, symptoms often are related to the menstrual cycle, suggesting a hormonal influence. A familial predisposition for the symptoms of IBS has been described, suggesting a genetic component.

Clinical Features

The diagnosis of IBS is defined by clinical criteria in a patient who has no other organic explanation for the symptoms. Several sets of clinical criteria have been published, one set of which is the Rome II criteria (Box 93-1). Patients with IBS experience symptoms intermittently, with the typical patient averaging symptoms on 1 of every 3 days. Complaints include abdominal pain, bloating, and constipation or diarrhea. Pain typically is relieved with defecation; pain that persists suggests another diagnosis. A mucoid discharge from the rectum often accompanies diarrhea. Upper gastrointestinal symptoms such as nausea and dyspepsia also can occur. Patients may present to the ED with an exacerbation of their previous symptoms or with a new abdominal complaint and often report that they are undergoing a period of stress. Physical examination may reveal mild abdominal tenderness that may be focal, often varying in location, or diffuse. IBS is subdivided into two categories: constipation-predominant and diarrhea-predominant.

Pain that is progressive, keeps the patient awake at night, or is associated with anorexia or significant abdominal tenderness suggests an alternate diagnosis. Fever, abdominal mass, and rectal bleeding also are atypical for IBS. In the absence of symptoms suggesting another diagnosis, the clinical criteria have a specificity ranging from 87 to 100%, although sensitivity may be only 60%. In patients determined to have IBS through correct use of the clinical criteria, follow-up evaluation over many years rarely leads to a change in the diagnosis.

Diagnostic Strategies

A final diagnosis of IBS usually is made in the primary care setting and not in the ED. A typical primary care evaluation for IBS may include a complete blood count, thyroid studies, stool exam for ova and parasites, evaluation for lactose intolerance, and possibly lower gastrointestinal endoscopy, although current approaches try to limit testing in cases in which the clinical picture is clearly IBS. The ED evaluation seeks to exclude other, more urgent causes for the patient’s symptoms. In this setting, testing for pancreatitis, hepatitis, biliary colic, or urologic disorders, including urolithiasis, may
be appropriate as indicated by the pattern of the presenting complaints.

### Differential Considerations

The differential diagnosis of symptomatic IBS depends on the predominant symptoms and includes a host of disorders (Box 93-2). Patients may present with pain, constipation, or diarrhea or any combination of the three.

#### Management

Not all patients with IBS require treatment. It is recommended that therapy be initiated only if symptoms diminish the quality of life. Because no curative therapy is available, treatment is directed toward the relief of symptoms. Diet, behavioral, and pharmacologic therapies all are used in IBS. Specific therapy will be determined by the type of IBS: constipation-predominant, diarrhea-predominant, or constipation-plus-diarrhea combination. Dietary suggestions include a low-fat diet, reduced nondigestible sugars, and avoidance of gas-forming foods, although none of these has any proven benefit. Fiber supplementation may aid constipation-predominant IBS.

Medications with antispasmodic activity, such as anticholinergics and calcium channel blockers, are used for abdominal cramping, and peripherally acting narcotics, such as loperamide, are used to reduce diarrhea. Osmotic laxatives such as lactulose sometimes are helpful in constipation. Tricyclic antidepressants have been effective in certain classes of patients with IBS. Serotonin receptor antagonists, such as alosetron, and prokinetic agents also are used (Box 93-3). Nonsteroidal anti-inflammatory drugs (NSAIDs) may worsen symptoms. Behavioral therapy may benefit patients who are unresponsive to medication, but high-quality evidence of its effectiveness is lacking. A role for nontraditional therapies such as arrowroot, artichoke leaf, and some Chinese traditional herbal medicines is supported by limited scientific evidence.

### Disposition

IBS is not a life-threatening disease and can be managed on an outpatient basis so long as other disorders have been excluded. The search for optimal therapy usually involves empirical trials until the correct fit is found. This process is best accomplished through a well-established primary care relationship. The disorder is chronic, but with appropriate therapy, many patients experience significant improvement in their quality of life.

## Diverticular Disease

### Perspective

Diverticular disease is an affliction of middle age that seems to be a direct consequence of the diet of modern Western civilization. Diverticular disease was virtually unknown in the Western world before the 20th century and is still rare in other cultures. In 1925, only 9% of people older than 50 years of age in the United States had diverticula; by 1968, the percentage had increased to 30%. Today it is estimated that 5 to 10% of people older than 45 years and 80% of people older than 85 years have diverticula. Diverticula are less common in people younger than age 40, representing only approximately 2 to 5% of all patients with the disease. The proliferation of this disease was coincident with the invention and widespread use of the flour rolling mill, which removes the fiber-containing outer part of the wheat kernel. This coincidence has prompted the labeling of diverticulosis as a “modern deficiency disease,” which is supported by the fact that adding fiber back into the diet seems to be protective against the development of diverticulosis. In rural Africa and Asia, where the diet is high in fiber, diverticular disease is virtually unknown.

Diverticulosis denotes the presence of diverticula in the colon. Most patients with this condition are asymptomatic. Diverticulitis denotes inflammation of diverticular tissue, which usually is painful.
Principles of Disease

The wall of the colon is penetrated at regular intervals by blood vessels, collectively known as the *vasa recta*, that supply the internal intestinal layers. The site of vessel penetration is apparently the weakest part of the colon wall, because it is at these sites that diverticula form. Although the exact pathogenic mechanism is unknown, the current theory is that diverticula form in response to increased intracolonic pressures generated when the colon is processing smaller, non–fiber-containing stools. Higher pressures lead to a herniation of colonic mucosa through the intestinal wall at the *vasa recta*, creating small, sac-like appendages. These appendages (diverticula) typically measure 5 to 10 mm in diameter but on rare occasions can grow into huge sacs measuring many centimeters across (*giant colonic diverticula*). Diverticula are asymptomatic in most affected persons, but symptoms are believed to develop when diverticula become obstructed, presumably with inspissated stool. When obstruction occurs, inflammation sets in and microperforations of the sac develop, resulting in inflammation of pericolonic fat and peritoneal irritation.

In the Western world, 85% of diverticular disease occurs in the left colon, usually the sigmoid. This is not the case in Japan, where right-sided diverticular disease is more common. Japanese-Hawaiians consuming a low-fiber Western diet have a significantly increased incidence of diverticular disease, but it remains in the right colon. This finding suggests that diet plays a significant role in the formation of diverticula but that the location of diverticula is genetically determined.

A spectrum of disease is observed in relation to diverticular inflammation. In *uncomplicated* diverticulitis, only the pericolonic fat is inflamed. With time, a phlegmon, abscess, or gross perforation may develop. Any extension of disease beyond the pericolonic fat is considered to represent *complicated* diverticulitis. The involved colonic segment may fistulize to any adjacent organ, most commonly the bladder (accounting for 65% of all fistulas). Adjacent bowel may become obstructed by mass effect from an abscess or may incur an inflammatory ileus. Recurrent episodes of diverticulitis can lead to strictures in the colon with subsequent colonic obstruction.

Diverticula also can bleed, presumably from erosion into the mucosal wall by dried stool trapped in the diverticular sac. Severe hemorrhage occurs in 3 to 5% of all patients with diverticulosis and accounts for approximately 40% of all instances of lower gastrointestinal hemorrhage. Bleeding notably occurs in the absence of inflammation and typically is painless. NSAID use is known to be associated with this complication.

Clinical Features

**Diverticulosis**

Commonly asymptomatic, patients with diverticulosis sometimes have nonspecific abdominal complaints including bloating, crampy pain, excessive gas, or a change in bowel habits. Diverticulitis will develop in approximately 10 to 30% of patients with diverticulosis; approximately 75% remain asymptomatic throughout their lifetime.

**Diverticulitis**

Because most diverticula found in persons in the Western world form in the left colon, the typical presentation of diverticulitis is persistent left lower quadrant pain and tenderness. Pain may be felt first in the hypogastrium before localizing to the left lower quadrant. Referred pain may occur in the penis, scrotum, or suprapubic region. Right-sided diverticulitis may manifest as right lower quadrant pain and is impossible to distinguish clinically from appendicitis. Additional findings suggest various complications: Diffuse tenderness is associated with gross perforation or abscess rupture; dysuria, with a colovesical fistula; mass, with an abscess; and vomiting or abdominal distention, with intestinal obstruction. Fecal matter or gas emanating from the vagina suggests a colouterine fistula.

Almost any adjacent organ can be involved in the inflammatory process. Patients recently diagnosed with diverticulitis who are being treated on an outpatient basis with oral antibiotics and who present to the ED with continuing or worsening symptoms should be evaluated for the possibility of an abscess.

Special care must be taken with elderly or immunocompromised patients, because clinical signs and symptoms are much less dramatic, even with more severe disease. Perforation is more common in these patients, manifests with less significant findings, and carries a high mortality rate.

**Diagnostic Strategies**

**Uncomplicated Diverticulitis**

The clinical diagnosis of uncomplicated diverticulitis can be made in a patient in the appropriate age range exhibiting focal left lower quadrant pain and tenderness in the absence of symptoms or signs that suggest an alternative diagnosis. No mass or peritoneal irritation should be encountered on examination, and the patient should otherwise appear well. If the patient fits this clinical picture, treatment can be initiated on an empirical basis, and no laboratory tests or diagnostic imaging is required. Ancillary tests are performed primarily to exclude alternative diagnoses or the presence of complicated diverticulitis. When the diagnosis is unclear, studies to exclude gynecologic, renal, hepatic, biliary, or pancreatic disease may be indicated, depending on the patient’s presentation and degree of distress. Computed tomography (CT) of the abdomen should be considered for elderly and immunocompromised patients to exclude the possibility of a subtle presentation of complicated diverticulitis.

**Complicated Diverticulitis**

**Abdominal Computed Tomography.** Abdominal CT is the preferred method of evaluation in complicated diverticulitis. CT has the advantage of evaluating the colon and the structures around it, so it can make the diagnosis of diverticulitis and simultaneously evaluate the extent of disease. CT also can be used to guide percutaneous drainage of diverticular abscesses. Findings on CT consistent with diverticulitis include the presence of diverticula, inflammation of pericolonic fat, thickening of the bowel wall to more than 4 mm, free abdominal air, and an abscess. CT also can help make an alternative diagnosis when diverticulitis is absent. CT is relatively noninvasive and is well tolerated by ill patients. Sensitivity and specificity for diverticulitis range from 69 to 95% and from 75 to 100%, respectively. Negative findings on CT scan cannot absolutely exclude diverticulitis. Small abscesses within the colon or mesocolon can be missed, as can the diverticula themselves. It also may be difficult to differentiate between carcinoma and diverticulitis on CT scan. Marked bowel wall thickening associated with diverticulitis looks like cancer; contrast enema or endoscopy may be required to differentiate between the two.

**Barium Enema.** Although double-contrast barium examination is the standard for the diagnosis of asymptomatic diverticula,
it should be avoided in the setting of diverticulitis. The potential for preexisting occult perforation and subsequent risk of barium peritonitis limits its usefulness. Barium enema may be used after the acute episode to exclude the diagnosis of carcinoma.

**Water-Soluble Contrast Enema.** A water-soluble contrast enema is the preferred method of imaging if a contrast enema study is needed in the acute setting. Water-soluble contrast material shows less detail than barium, but this modality is still useful. Findings consistent with diverticulitis include the presence of diverticula along with extravasation of contrast material into an abscess cavity or into the peritoneum. This study also can show a fistula or evidence of compression of the colon by an extrinsic mass. Because contrast material usually collects only in the intestinal lumen, contrast enemas give less information than CT about the extent of disease outside of the colon.

**Ultrasonography.** Ultrasound examination can detect various pathologic features characteristic of diverticulitis, including fluid collections around the colon, thickened hypoechoic bowel wall, or hyperechoicity adjacent to the bowel wall that suggest pericolonic inflammation. Tenderness to palpation over an abnormal-appearing colon suggests that the colon is the source of the patient’s pain. Diverticula can occasionally be visualized by ultrasound exam. As is often the case, the sensitivity of ultrasound imaging for these findings varies significantly with the experience of the operator. Because gas interferes with ultrasound imaging, adequate visualization of the bowel can be a problem. Currently, the role for ultrasonography in the evaluation of diverticulitis is not well defined.

**Endoscopy.** Endoscopy is limited in the acute setting by its more invasive nature, the risk of perforation, and the logistics of arranging this procedure emergently. Although the endoscope affords visualization of diverticula and other pathologic processes within the lumen of the colon, it does not permit evaluation of the extent of extracolonic disease.

**Plain Radiography.** Plain films of the abdomen are not likely to be helpful in the diagnosis of diverticulitis unless either intestinal obstruction or perforation is suspected.

### Differential Considerations

In a patient who presents with more serious disease, making the correct diagnosis usually poses no great dilemma because more extensive laboratory testing and diagnostic imaging typically have been performed. In a patient with milder disease, in whom a tentative diagnosis of diverticulitis may be based on clinical grounds alone, the differential diagnosis presents more of a challenge. An important consideration is whether or not the patient has colonic carcinoma; however, it usually is safe to wait until after the acute episode has resolved to investigate this possibility. Additional diagnoses to consider include colitis (either inflammatory or ischemic); ureteral stones; intestinal hernia; and pelvic pathology, including ectopic pregnancy or pelvic inflammatory disease, and ovarian pathology with or without ovarian torsion. Appendicitis should be suspected when symptoms are predominantly right-sided. Diffuse abdominal pain should prompt an evaluation for other life-threatening problems, including leaking abdominal aortic aneurysm, peritonitis, hemoperitoneum from ectopic pregnancy, and bowel obstruction.

### Management

#### Diverticulitis

All patients diagnosed with diverticulosis should be placed on a high-fiber diet, which has been shown to reduce abdominal symptoms and recurrent bouts of diverticulitis. It is not known if the common advice to avoid foods that may obstruct diverticula, such as nuts and small seeds, is of any real merit.

**Uncomplicated Diverticulitis**

Uncomplicated diverticulitis in an immunocompetent, nonelderly patient can be managed on an outpatient basis with oral antibiotics. Coverage for gram-negative aerobic and anaerobic bacteria is required. Patients may be placed on a liquid diet for comfort, although this is not mandatory. NSAIDs or narcotics are appropriate for pain control, but many experts recommend avoiding morphine sulfate because it increases intraintestinal pressure, which theoretically can precipitate perforation. A high-fiber diet prevents recurrent diverticulitis for 5 years in 70% of patients.

Patients with significant comorbid illness or other problems, including inability to tolerate oral liquids, poor social support, and inability to comply with follow-up in a reasonable time frame (2 to 3 days), should be considered for hospital admission. Hospitalized patients generally are treated with intravenous antibiotics and placed on bowel rest, although patients hospitalized for psychosocial reasons can be treated with oral medications.

**Complicated Diverticulitis**

Patients with complicated diverticulitis should be admitted to the hospital and treated with intravenous antibiotics. Emergent surgical intervention is indicated for all patients with peritonitis or perforation. Newer techniques using a laparoscopic approach with lavage and biologic glue have supplanted open surgical techniques in some patients. Continuing clinical decline, sepsis resistant to medical management, or a high level of antimicrobial resistance indicates the need for surgical intervention.

### Uncomplicated Diverticulitis

- **Trimethoprim-sulfamethoxazole**, double-strength tablets bid, and **metronidazole**, 500 mg q6h or
- **Ciprofloxacin**, 750 mg bid, and **metronidazole**, 500 mg q6h or
- **Amoxicillin-clavulanate extended-release**, 1000/62.5 mg, 2 tabs bid or
- All oral regimens should be taken for 7 to 10 days.

### Complicated Diverticulitis

- **Ticarcillin-clavulanate**, 3.1 g IV q6h or
- **Ampicillin-sulbactam**, 3 g IV q6h or
- **Ciprofloxacin**, 400 mg IV q12h, and **metronidazole**, 1 g IV q12h

*Severe Infection*

- **Ampicillin**, 2 g IV q6h, and **metronidazole**, 500 mg IV q6h, and (gentamicin, 7 mg/kg q24h, or ciprofloxacin) 400 mg IV q12h or
- **Imipenem**, 500 mg IV q6h

of suspicion for carcinoma warrants urgent surgical consultation. Small abscesses (less than 5 cm in diameter) are treated with intravenous antibiotics alone (see Box 93-5), whereas larger abscesses are drained either percutaneously with imaging guidance or surgically. Bowel obstruction during an attack of diverticulitis usually is self-limited and resolves with conservative management. Chronic recurrent diverticulitis can result in stricture, which necessitates surgical intervention. Fistulas usually are repaired surgically. A significantly dilated cecum (to greater than 10 cm in diameter) or gas in the bowel wall should prompt early consultation with a surgeon about the possibility of bowel necrosis and impending perforation.

Definitive Management

It is not known whether medical or dietary treatment is of benefit in diverticulitis. The only proven way to eradicate diverticula is to remove the affected segment of colon surgically. Most patients who recover from their first attack of diverticulitis are likely to remain asymptomatic for many years. With subsequent attacks, the likelihood of recurrence increases. Elective resection of diverticula generally is reserved for patients who have had more than one attack of diverticulitis. According to some experts, younger patients (i.e., younger than 40 years of age) should undergo elective resection after their first bout of diverticulitis because of concerns about a higher risk for a second attack, but this recommendation is controversial, with recent evidence suggesting that outcomes are better without surgery. Most resections can be done laparoscopically with a single-stage procedure (no colostomy). Estimates on recurrence of diverticular disease after resection vary, ranging from 3 to 27%.

Disposition

Uncomplicated Diverticulitis

Nonelderly and immunocompetent patients may be sent home on oral antibiotics with referral for follow-up evaluation in 2 to 3 days to determine the success of treatment. Patients are cautioned to return to the ED if their condition worsens. Patients not significantly improved at follow-up should undergo diagnostic imaging to look for an abscess and be hospitalized for intravenous antibiotic therapy. Of patients treated medically for their first attack of diverticulitis, 95% remain symptom-free for the next 2 years, and 80 to 90% remain symptom-free permanently. Patients with recurrent episodes of diverticulitis should be referred to a surgeon for outpatient consultation for elective resection. All patients should undergo an evaluation for colon cancer when the acute episode has resolved, because the incidence of coexistent cancer has been reported to be as high as 9%.

Complicated Diverticulitis

All patients require hospitalization for intravenous antibiotic therapy and bowel rest. Most patients (65 to 85%) recover with medical management alone; the rest require surgical intervention. Outcomes generally are good, with mortality rates ranging from 1 to 6% for all patients, increasing to 12 to 18% for patients requiring surgery.

LARGE BOWEL OBSTRUCTION

Perspective

Large bowel obstruction (LBO) is much less common than small bowel obstruction, but LBO is a more ominous condition because it frequently is associated with malignant disease. One half of all operative cases involving LBO in the United States are the result of colorectal cancer. Adhesions, a common cause of small bowel obstruction, cause only 1 to 8% of LBOs. Other causes of LBO include volvulus, diverticular disease, fecal impaction, strictures (often related to inflammatory bowel disease or chronic colon ischemia), adhesions, hernia, and pseudo-obstruction. Most causes are managed surgically, but pseudo-obstruction responds well to medical management alone.

Principles of Disease

When mechanical obstruction is secondary to an obstructing lesion, either inside the bowel (carcinoma) or outside the bowel (diverticular abscess, volvulus), the bowel becomes increasingly dilated with air, and fluid that cannot be passed distally. As the distention increases, the intraluminal pressure increases. When intraluminal pressure approaches systolic blood pressure, blood flow to the bowel wall is compromised and edema sets in, with subsequent transudation of fluid into the lumen. Transudation along with decreased resorption of intraluminal fluid leads to dehydration. Eventually, as arterial flow to the bowel wall is compromised, ischemia and gangrene develop. Translocation of bacteria from compromised bowel can lead to sepsis. Perforation of the bowel wall follows if the process is not interrupted.

Pseudo-obstruction, also called Ogilvie’s syndrome, occurs through a completely different mechanism. Pseudo-obstruction is defined as LBO in which no obstructing lesion can be identified. This condition usually is found in patients with significant acute comorbid conditions. Patients typically have a history of significant spine or retroperitoneal trauma, severe electrolyte disturbances, or narcotic exposure. Although the exact mechanism is unknown, it is believed to involve malfunction of autonomic control of the bowel. Normal balance between parasympathetic and sympathetic input is disrupted, resulting in changes in motility that lead to obstruction. The pathophysiologic changes observed with pseudo-obstruction are the same as those described for mechanical obstruction.

Clinical Features

The typical presenting complaints in LBO are abdominal pain, abdominal distention, obstipation, and vomiting. The time frame within which these symptoms develop varies in accordance with the rapidity of onset of the obstruction. LBO associated with a volvulus can develop rapidly, whereas obstruction from cancer tends to be of gradual onset. Patients presenting later in the course of obstruction may be significantly dehydrated. Significant fever or tachycardia should prompt an investigation for gangrene and perforation. A palpable abdominal mass may represent a tumor, an abscess, or simply distended bowel. A rectal examination is helpful to look for an obstructing rectal mass or a large volume of hard stool in the rectal vault consistent with fecal impaction.

Diagnostic Strategies

Electrolyte measurements may be helpful in guiding fluid and electrolyte replacement therapy. A significantly elevated white blood cell (WBC) count should raise suspicion for gangrenous bowel, whereas anemia suggests the possibility of colorectal cancer.
**Chapter 93 / Disorders of the Large Intestine**

**Figure 93-1.** Plain radiographs showing large bowel obstruction at the sigmoid colon caused by carcinoma. A, Erect view. B, Supine view.

*Plain Radiography.* A distended colon is the hallmark of LBO (Fig. 93-1), although small bowel may be distended as well if the ileocecal valve is incompetent. In some cases, gas-filled small bowel may obscure visualization of the colon, leading to the misdiagnosis of small bowel obstruction. An abrupt cutoff at the distal end of the obstructed colonic segment suggests a possible pseudo-obstruction. A cecal diameter exceeding 12 cm is of concern because this finding is associated with a higher risk of perforation. The actual location and cause of the LBO usually are not evident on plain films.

*Computed Tomography.* CT is a valuable tool for determining the cause of the obstruction, especially if the cause is a diverticular abscess or intussusception. CT typically is less helpful in pseudo-obstruction, in which either colonoscopy or a water-soluble contrast enema study is needed to make the diagnosis.

*Colonoscopy and Water-Soluble Contrast Enema* Patients in whom the cause of obstruction is not known and who are not candidates for urgent surgical intervention should undergo either a water-soluble contrast enema study or colonoscopy to determine the etiology of the obstruction. This diagnostic strategy is much more accurate in ruling out pseudo-obstruction than imaging.

**Differential Considerations**
The most common causes of LBO are colorectal cancer (53%), volvulus (17%), diverticulitis (12%), and compression from metastatic disease (6%). Other, less common causes are strictures, incarcerated hernia, fecal impaction, adhesions, and pseudo-obstruction.

**Management**
Management in the ED is directed at relief of symptoms. Rehydration, electrolyte replacement, and pain management are the first concerns. Gastric decompression with a nasogastric tube may be helpful in cases in which vomiting is prominent or when there is evidence of significant fluid or gas buildup in the small intestine. No additional fluid or solids should be administered by mouth. Antibiotics are indicated if gangrene or perforation is suspected (see Box 93-5). Definitive management depends on the cause of the obstruction, which may or may not be determined in the ED. Select diverticular abscesses may be drained percutaneously, whereas a sigmoid volvulus or pseudo-obstruction can be decompressed endoscopically. Diverticular disease and sigmoid volvulus eventually necessitate an elective surgical procedure to prevent recurrence, although this often can be delayed. Carcinoma, cecal volvulus, strictures, intussusception, adhesions, and hernias are dealt with primarily surgically.

So long as the possibility of perforation is not an immediate concern, pseudo-obstruction is managed for the first 24 hours with bowel rest, hydration, and management of any acute comorbid conditions. If the colon fails to decompress, colonoscopic or pharmacologic intervention (neostigmine) may be attempted, with surgery reserved for refractory cases.

Fecal impaction generally is managed definitively in the ED through digital disimpaction or an enema. Particularly helpful are retention enemas, for which the patient retains the enema fluid in the rectum for 15 minutes or longer. Occasionally disimpaction is technically difficult enough to warrant general anesthesia.
PART III
■ Medicine and Surgery

Section Five
• Gastrointestinal System

In the absence of gangrenous bowel, the risk of death is exceed 50% in patients who present with gangrenous bowel. Disease of older persons. Mortality rates with sigmoid volvulus all other areas of the colon. Sigmoid volvulus typically is a sigmoid colon and the cecum, although volvulus can occur in other areas of the colon. Sigmoid volvulus typically is a disease of older persons. Mortality rates with sigmoid volvulus exceed 50% in patients who present with gangrenous bowel. In the absence of gangrenous bowel, the risk of death is approximately 10%.

Principles of Disease

Sigmoid Volvulus

The anatomic requirement for a sigmoid volvulus is a long, redundant section of sigmoid that is attached to the abdominal wall by a narrow strip of mesentery. The narrow attachment allows the mesentery to twist on itself, thereby obstructing the intestinal lumen. It is not clear whether this is a congenital condition or occurs as part of the aging process. After the colon twists on itself, the proximal colon continues to force gas and liquid into the obstructed segment, causing a sometimes massive dilation of the distal colon. Significant electrolyte disturbances can occur secondary to third spacing, and respiratory compromise occasionally occurs from massive abdominal distention. If the condition is left untreated, the vascular supply can become compromised, resulting in gangrene and perforation.

The exact precipitator of an acute episode of volvulus is not clear. A high-fiber diet has been implicated, because a significant increase in the disease is noted in patients who are switched to a high-fiber diet. Chronic constipation has been associated with volvulus, but it is unclear how the two conditions are related. Residents of long-term care facilities and patients with neurologic or psychiatric diseases also are predisposed to sigmoid volvulus, possibly as a result of alterations in colonic motility. No association with previous surgery has been observed. Women seem to be at a higher risk for cecal volvulus during pregnancy, presumably because of crowding of the abdominal cavity by the enlarged uterus. The condition is still rare, however, occurring in approximately 1 per 1 million pregnancies.18

Cecal Volvulus

As in sigmoid volvulus, a mobile segment of cecum is a prerequisite to the disease. This mobility seems to be due to a congenitally incomplete fusion of the cecal mesentery to the posterior abdominal wall. Cadaver studies show that 10% of the adult population have ceca that are mobile enough to cause torsion.17 In 10% of the cases, cecal volvulus is due to a variant called cecal bascule, in which the cecum does not twist but merely folds over on itself; symptoms and management are the same.15 The tendency for cecal volvulus may be related to “maneuvering room” available for the colon within the abdomen. Persons with less space in the abdomen for the colon to move about seem to be more predisposed to volvulus in general. Gangrene of the bowel is common and occurs in 20% of patients with cecal volvulus.19

Clinical Features

Sigmoid Volvulus

The hallmark of sigmoid volvulus is the triad of abdominal pain, distention, and constipation. The extent to which the sigmoid colon can twist on itself is recognized to vary, so the presentation of sigmoid volvulus will vary accordingly, from subtle to dramatic. The clinical picture may range from one of minor abdominal discomfort that has been present for many days to an acute onset of severe abdominal pain associated with gross abdominal distention and unstable vital signs. Sometimes the diagnosis of sigmoid volvulus is not made until the patient has been hospitalized for some time. In many instances, the history may be suggestive of previous episodes of volvulus that self-reduced.

The physical examination may reveal a distended tympanic abdomen, often with most of the distention in the upper abdomen but primarily on one side. Patients may look remarkably well for the amount of distention that is encountered. Significant abdominal pain, fever, lack of bowel sounds, peritonitis, or cardiovascular instability suggests gangrenous bowel and should prompt immediate surgical consultation. The absence of these findings does not exclude gangrene, however. The duration of symptoms alone is not predictive of gangrene of the bowel.

Cecal Volvulus

The clinical triad of abdominal pain, distention, and constipation seen in sigmoid volvulus also is seen in cecal volvulus, but many patients with cecal volvulus lack one or more of these findings. Vomiting is seen in only approximately 50% of patients.

Diagnostic Strategies

Sigmoid Volvulus

The diagnosis of sigmoid volvulus can be made on the basis of findings on plain radiographs in most cases. A grossly distended loop of colon lacking haustral markings is typical and is seen just as often on the right side of the abdomen as on the left (Fig. 93-2). The bowel may have the appearance of a “bent inner tube.” Free air may be seen on an upright chest film or lateral decubitus radiograph of the abdomen in patients who have a perforation. Gas backing up into the rest of the colon may obscure the typical appearance of sigmoid volvulus on plain radiographs, leading to a significant number of nondiagnostic studies. Cecal volvulus and bowel obstruction from other causes may have a similar radiographic appearance. When the diagnosis is in doubt, contrast enema may be helpful. Contrast material fills up the colon to the tapering point of torsion, giving a “bird’s beak” appearance to the column of contrast material (Fig. 93-3). Sigmoidoscopy is diagnostic in many cases, visualizing a spiral sphincter–like twist.
in the colonic mucosa. CT scan, when used, also is highly accurate, but most diagnoses can be made without it.

Cecal Volvulus

Plain radiographs often are helpful in establishing a diagnosis of cecal volvulus, but the findings are not definitive in 50% of cases. The cecum should be markedly dilated and may contain an air-fluid level. The small bowel often is distended as well. In contrast with the picture in sigmoid volvulus, the distal colon should have a paucity of gas (Fig. 93-4). The classic “coffee bean” sign, a large oval gas shadow with a line down the middle representing bowel bent over on itself, may be seen in the midabdomen. Free air suggests perforation and requires emergent surgical consultation. A common mistake is misinterpreting the plain radiograph as showing a sigmoid volvulus. If the diagnosis is unclear, a contrast enema is helpful in showing the site of torsion. Ultrasound imaging generally is unhelpful. On CT, a mesocolon “whirl sign” may be seen, indicating a twisted segment of mesentry. In many cases, cecal volvulus is definitively diagnosed only at surgery.

Differential Considerations

Any process that causes LBO may mimic volvulus.

Management

Sigmoid Volvulus

Although spontaneous reduction of a sigmoid volvulus can occur, it is infrequent enough to mandate a proactive approach to treatment. If clinical evidence of gangrenous bowel is lacking, endoscopic detorsion should be attempted by an experienced operator. Using the endoscope, the bowel is first examined for any signs of gangrene. If the bowel is healthy,
the twisted, obstructed proximal end of the bowel lumen is identified, and a lubricated rubber tube is inserted through the obstruction. With decompression of gas and liquid stool, the bowel is able to undergo self-detorsion. Endoscopic decompression is successful in 50 to 90% of cases.\textsuperscript{15,20} If the patient has gangrenous bowel or the volvulus does not respond to endoscopic decompression, surgery is indicated. Recurrence rates are estimated at 60%; elective resection of the redundant sigmoid is recommended after resolution of the acute episode. The mortality rate for sigmoid volvulus is 20% overall and exceeds 50% in the subgroup of patients with gangrene.

Cecal Volvulus

The proximal nature of the cecum makes it unavailable for endoscopic manipulation, so detorsion is done surgically. After detorsion, the cecum typically is fixed to the abdominal wall, or the redundant section is resected.\textsuperscript{21} Recurrence is rare after resection.

Disposition

All patients with volvulus require hospitalization for detorsion and surgical intervention to prevent recurrence.

\section*{INTUSSUSCEPTION}

\subsection*{Perspective}

Intussusception in adults is rare, accounting for only 1 to 5% of cases of adult bowel obstruction. Most adult intussusceptions (80%) are of the small bowel. Although only 10% of children have a pathologic lesion as the cause of the intussusception, 90% of adults do. In the colon, these lesions are malignant 50 to 80% of the time, as opposed to the small bowel, in which malignant lesions are present approximately one third of the time.\textsuperscript{22} In adults, the intussusception often is unsuspected before being revealed on a CT scan or during laparotomy. The condition occurs over a wide variety of ages, with a mean age at presentation of 65 years.\textsuperscript{23}

\subsection*{Principles of Disease}

The exact mechanism of intussusception is unknown, but it is believed that a lesion (the “lead point”) changes the motility properties of the intestine, allowing a proximal segment to invaginate into a more distal segment. As peristaltic activity pushes the invaginated segment along with its mesentery and mesenteric blood vessels down the bowel, the blood supply to the segment can be compromised, and ischemia may occur. Edema associated with the intussusception can lead to a mechanical obstruction of the bowel.

\subsection*{Clinical Features}

Intussusception in adults manifests in one of two patterns. The most common is that of acute partial intestinal obstruction. Less than 20% of intussusceptions cause complete obstruction.\textsuperscript{24} With this pattern, the typical presenting complaint is abdominal pain. Vomiting, bleeding, and constipation may be present but often are not. The abdomen may be distended, and bowel sounds are decreased. A mass is seldom palpated; the classic triad of abdominal pain, mass, and heme-positive stools noted in children is rarely found in adults. The second presentation is much more subtle, with intermittent abdominal pain for months or years. The diagnosis usually is made only when the pain becomes unrelenting or has been recurrent enough to prompt imaging.

\subsection*{Diagnostic Strategies}

\textbf{Plain Radiography.} Plain radiography is a reasonable screening test in a patient suspected of having bowel obstruction, but the radiographs usually show only nonspecific large bowel dilatation.

\textbf{Computed Tomography.} Typically used in the evaluation of abdominal pain and bowel obstruction, CT usually is the most useful test in suspected intussusception but may not detect the actual intussusception in as many as one half of the cases.\textsuperscript{22,23}

\textbf{Ultrasound Examination.} Ultrasonography also is helpful in detecting intussusception but is not as useful as CT in excluding other diagnoses. A transverse view of the intussusception has a donut or target shape, with multiple concentric rings. A longitudinal view of the intussuscepted segment has an ultrasound appearance similar to that of a kidney (“pseudo-kidney sign”), with a bright central area surrounded by a darker outer layer.

\textbf{Barium Enema.} Although a barium enema study can demonstrate intussusception and even reduce it, it is a less desirable study than either CT or ultrasound examination for initial diagnosis. In contrast with that in children, reduction of intussusception in adults is not desired before surgery because of concerns about spreading malignant cells from potentially malignant lead points. Barium enema should not be performed in patients suspected of having a bowel perforation.

\textbf{Colonoscopy.} Colonoscopy is helpful in defining the lesion causing intussusception but does not usually detect the intussusception itself.

\subsection*{Differential Considerations}

The differential diagnosis includes other causes of bowel obstruction.

\subsection*{Management}

Surgery is required in most cases. ED care is supportive and aimed at optimizing fluid status, recognizing gangrene or perforation, administering antibiotics if compromised bowel is suspected, and securing surgical consultation in the appropriate time frame. Because of the high incidence of malignancy, reduction often is not attempted in adults before surgical exploration.\textsuperscript{23} Occasionally, intussusception may resolve spontaneously, but an evaluation to exclude a pathologic lead point still must be undertaken.

\subsection*{Disposition}

Because of the surgical nature of this disease, all patients require hospitalization. Operative mortality tends to be minimal.\textsuperscript{22}

\section*{INFLAMMATORY BOWEL DISEASE}

\subsection*{Perspective}

Inflammatory bowel disease (IBD) includes two clinically similar but distinct diseases: Crohn’s disease (CD) and ulcerative colitis (UC). Both diseases are characterized by chronic and unpredictable relapsing inflammation of the gastrointestinal tract from causes that have not been definitively identified. Significant morbidity occurs from acute exacerbations of inflammation. It is estimated that more than 1 million people in the United States are affected by IBD.\textsuperscript{25} Cases are divided approximately equally between CD and UC, with a combined...
annual incidence of approximately 10 cases per 100,000.26 The long-term management of IBD is a complex, stepwise process that involves multiple medications and surgery. The goals of the ED evaluation are to (1) recognize potential new cases of IBD, (2) consider and exclude serious complications in patients with IBD, and (3) identify those patients with IBD who need in-hospital care. Treatment plans are best developed in consultation with a physician experienced in the long-term management of IBD. Although life expectancy is slightly decreased for patients with CD, it is normal for patients with UC.27

Principles of Disease

Ulcerative Colitis

UC causes inflammation and ulceration throughout the colon and rectum, but spares the small intestine. Inflammation is more superficial than that found in CD. Typically, the inflammation exists as one continuous lesion originating in the rectum and extending a variable distance into the colon, although more recently, cases of discontinuous disease (“skip lesions”) similar to that in CD have been reported in UC.28 The concordance rate between identical twins is low (6 to 14%), suggesting that factors other than genetics are involved in the development of UC.29 Stress can trigger exacerbations, and cigarette smoking has a protective effect, suggesting environmental factors at work. Appendectomy at an early age is protective, suggesting that the immune system may play a role. In animal models of IBD, the disease does not occur in animals that are devoid of normal bowel flora, suggesting that bowel flora are a necessary ingredient for disease.30 One unifying theory is that UC represents a genetic predisposition to development of an inflammatory reaction to normal intestinal flora—in essence, losing the normal tolerance to these bacteria.

Crohn's Disease

The cause of CD is unknown, but genetic, environmental, immunologic, and infectious processes all have been implicated as possible causative or contributory factors.26 Concordance between identical twins is 45 to 50%, suggesting a strong genetic predisposition that is modified by other factors.29 Africans have a low incidence of CD, but African Americans have an incidence similar to that in white Americans.26 The first genetic mutation associated with CD was described in 2001 and is associated with 10 to 20% of cases of CD.30 An association between a strain of Mycobacterium and CD has been hypothesized, with the evidence being convincing enough to spur legislation in the United Kingdom to eradicate this potential pathogen from the food chain, but recent failures in a randomized controlled trial of antituberculosis medications in CD cast serious doubts on any causal relationship.31,32 Although the onset of the disease can be at any time of life, CD affects primarily young patients, with onset of disease typically in the teens and 20s. Inflammation in CD is deep, involving the entire colonic wall. The disease is not limited to the colon and rectum as it is in UC but may affect any part of the gastrointestinal tract. CD most often involves the distal small intestine and colon and less commonly the esophagus, duodenum, or stomach.33 Because of the transmural nature of the inflammation, the development of intestinal strictures or fistulas to adjacent organs is a potential complication.

Clinical Features

Typical presenting complaints in patients with IBD include abdominal pain, often crampy, and tenesmus with loose or diarrheal stools. Blood may be present in the stool. Patients with CD may have a history of nocturnal diarrhea, a complaint that helps differentiate CD from patients who have IBS. Weight loss is common. The physical examination may reveal significant abdominal tenderness or an abdominal mass representing an abscess. Patients with CD may have fissures, ulcerated hemorrhoids, strictures, or cutaneous abscesses around the anus. Extraintestinal manifestations include inflammatory conditions of the skin, eyes, and joints. In children, growth and sexual development may be affected. Onset of symptoms usually occurs before the age of 30 years,25 although the diagnosis can be difficult to make in the early stages.

Patients often present to the ED with a known diagnosis of IBD and worsening abdominal symptoms. A common reason for relapse is interruption of the medications that have kept the disease in remission. Many patients become compliant during quiescent periods and stop taking such medications. IBD requires continuous, lifelong maintenance therapy. Adherence to therapy has been shown to reduce the risk of acute attacks and cancer.25 Common complications of IBD include formation of fistulas, strictures, and abscesses; less common but life-threatening complications include fulminant colitis, toxic megacolon, and intestinal perforation.

Toxic Megacolon

Toxic megacolon is a pathologic dilatation of the colon resulting from inflammation of the smooth muscle layers of the intestine. Muscle inflammation leads to paralysis, dilation, and eventually perforation if left untreated. The hallmark of toxic megacolon is colonic dilatation in a patient with a known inflammatory condition of the colon who appears systemically toxic. Presence of inflammation and toxicity differentiates toxic megacolon from other disorders that cause colon dilatation, including mechanical obstruction, pseudo-obstruction, and congenital or acquired megacolon.

Toxic megacolon typically is associated with IBD or infectious colitis. The triggering event may be recent ingestion of anticholinergics, antimotility agents, narcotics, or antidepressants. Patients usually have experienced symptoms of colitis, which often are severe, for several days before the onset of toxic megacolon. Abdominal pain, fever, tachycardia, and abdominal distention are present. Plain radiographs are diagnostic and show a colon with a diameter of 6 cm or greater, although this feature may not be present in early stages. Treatment includes aggressive fluid hydration, intravenous corticosteroids, antibiotics covering bowel flora (see Box 93-5), and an evaluation for potential intestinal infections, especially in immunocompromised patients. The mortality rate has decreased over the past 4 decades to less than 2% as a result of the early recognition and aggressive treatment.

Diagnostic Strategies

No specific laboratory tests available to diagnose IBD are available, although recent tests targeting antibodies to Saccharomyces cerevisiae or antineutrophil cytoplasm help to differentiate between CD and UC.27 Laboratory abnormalities may be due to a variety of reasons. Electrolyte abnormalities may be secondary to significant diarrhea, or anemia may occur from bloody stools. The erythrocyte sedimentation rate can be elevated and useful for categorizing the severity of the disease. Stools contain fecal leukocytes, but findings on stool cultures and ova and parasite examinations should be normal. Plain radiography is not helpful in the diagnosis of uncomplicated disease but may show bowel obstruction, toxic megacolon, or free air from a perforation (Fig. 93-5). The use of plain films should be limited to patients suspected of having
these complications. Contrast studies can reveal lesions suggestive of IBD, including ulcerations of the mucosal surface, fistulas, and strictures. In Europe, where ultrasound technicians are more experienced in its application, ultrasonography is used to identify active disease and to look for complications. Ultrasonography is used much less commonly in the United States. Magnetic resonance imaging can locate affected bowel segments and identify fistulas, stenoses, and abscesses. CT is the best study routinely available to evaluate extraluminal complications. CT colonography (“virtual colonoscopy”), although good at identifying cancerous lesions of the colon, does not show the typical lesions of IBD. Endoscopic evaluation with biopsy usually is required to confirm the diagnosis.

Differential Considerations
Symptoms and signs are protean and overlap with those of many common abdominal conditions, including appendicitis, infectious colitis, ischemic colitis, radiation colitis, diverticular disease, cancer, and bowel obstruction.

Management
Medical management is the mainstay of therapy for most patients with IBD. In general, patients are maintained on 5-aminosalicylic acid (5-ASA) agents while asymptomatic and then steroids are added once symptoms recur. Once remission is obtained, steroids are discontinued and the patient is once more maintained on 5-ASA agents. If remission is not obtained with steroids, other agents such as antimetabolites and immunosuppressants are used (Box 93-6). The choice of agents depends on classification of the disease as either mild to moderate or severe (Box 93-7). Surgery is reserved

**Figure 93-5.** Toxic megacolon secondary to ulcerative colitis. The smooth indentations seen along the margin of the colon represent pseudopolyps.

**Box 93-6** Medications Used in the Treatment of Inflammatory Bowel Disease

5-Aminosalicylic Acid Agents
- Sulfasalazine
- Mesalamine

Antibiotics
- Metronidazole
- Ciprofloxacin
- Rifaximin
- Tobramycin

Corticosteroids
- Prednisone
- Hydrocortisone
- Methylprednisolone
- Budesonide

Antimetabolites
- Azathioprine
- 6-Mercaptopurine
- Methotrexate

Immunosuppressants
- Cyclosporine
- Anti–Tumor Necrosis Factor Antibodies
- Infliximab

**Box 93-7** Disease Severity Criteria in Inflammatory Bowel Disease

**Ulcerative Colitis**

*Mild Disease*
- >4 stools per day
- Stools may contain some blood
- No systemic signs of toxicity (fever, tachycardia, anemia, elevated erythrocyte sedimentation rate)

*Moderate Disease*
- >4 stools per day
- Minimal signs of toxicity

*Severe Disease*
- >6 bloody stools per day
- Signs of systemic toxicity

**Crohn’s Disease**

*Mild*
- Patient ambulatory and able to eat
- No toxicity
- No significant abdominal pain or mass

*Moderate*
- Mild disease that has failed to respond to treatment
- Patient may have some systemic toxicity

*Severe*
- Persistence of symptoms during corticosteroid therapy
- High fever, persistent vomiting
- Intestinal obstruction
- Rebound tenderness
- Cachexia
- Abscess

for patients with severe disease who do not respond to medical therapy or for complications such as obstruction or fistula formation.

5-ASA agents are the first line of therapy for disease that is not severe. These agents can be administered orally, or rectally if the disease is in or near the rectum. Sulfasalazine, one of the original drugs in this category, is limited by sulfide toxicity at higher doses and has serious side effects including bone marrow suppression. A newer 5-ASA derivative, mesalamine, has less toxicity, allowing higher dosages. When IBD goes into remission after an acute flare, the patient may be continued on 5-ASA derivatives for maintenance therapy.

Antibiotics may be used for the primary treatment of IBD as well, but their use in IBD is controversial. Evidence supporting antibiotic use is stronger in CD than in UC. Metronidazole and ciprofloxacin are the most common antibiotics used, with some evidence suggesting that tobramycin or rifaximin may be beneficial as well.34

Oral corticosteroids are used in patients with moderate to severe disease or patients whose IBD is unresponsive to a 5-ASA agent. Steroids should be tapered when remission is achieved to avoid typical steroid side effects. Intravenous corticosteroids are reserved for hospitalized patients with severe disease. Budesonide, a newer oral corticosteroid, is degraded on its first pass through the bloodstream and has fewer systemic side effects.

The immunomodulating drugs azathioprine and 6-mercaptopurine are used in patients resistant to other therapies or to wean steroid-dependent patients off steroids. Patients on these medications should be assessed for bone marrow suppression and pancreatitis.35

The immunosuppressant agent cyclosporine is used in severe cases, often when patients are not surgical candidates. Although most patients tolerate it well, cyclosporine has significant potential toxicity, including myelosuppression, electrolyte disturbances, and hepatic and nephrotoxicity.25 Opportunistic infections including Pneumocystis pneumonia have been known to occur.29

Infliximab, an antibody to human tumor necrosis factor-α, is useful in advanced cases of IBD. It generally has a benign side effect profile,26 but carries an increased risk of opportunistic infections, including tuberculosis and fungal infections. Surgery is reserved for patients with severe disease refractory to medical management or for patients with complications such as intestinal obstruction, significant bleeding, abscess, or fistula. A colectomy is curative for UC and improves quality of life, but there is no curative surgery for CD. Extraintestinal manifestations usually respond to therapy for intestinal disease.27,36

Disposition

Consultation with a gastroenterologist is recommended before patient disposition. Most patients with uncomplicated mild to moderate exacerbation of IBD need only to restart their maintenance therapy if it was interrupted, or to add oral corticosteroids to their regimen. Patients with severe disease or those in whom oral corticosteroids have failed to effect improvement need hospitalization for administration of parenteral corticosteroids.27 Bowel rest does not seem to be beneficial except as preparation for surgical intervention.27 Emergent surgical consultation should be sought for life-threatening hemorrhage, evidence of perforation, or toxic megacolon. Urgent surgical intervention is indicated if the bowel is obstructed. Abscesses may be treated percutaneously with imaging guidance or surgically.29 Chronic fistulas initially are treated medically.29 After hospital discharge, close follow-up by the physician monitoring the patient’s disease is indicated to ensure that remission is achieved in a timely fashion and that the patient complies with the suppressive therapy after the acute event. For patients in remission, endoscopic monitoring for cancer is required on an ongoing basis, although the optimal frequency of examination has not yet been defined.35 The estimated prevalence of cancer among patients with CD is significant at 2%,33 and patients with UC have a 15 times greater risk for the development of colorectal cancer than in the general population.29

■ COLONIC ISCHEMIA

Perspective

Colonic ischemia is the most common of the intestinal ischemic disorders. Estimates place the incidence of colonic ischemia at 1 of every 2000 hospitalizations. Its presentation overlaps with many other significant abdominal diseases, and it is difficult to diagnose without endoscopic visualization of the colonic mucosa. Although elderly persons are most at risk, with 90% of cases in those older than 60 years of age, the condition can occur in all age groups.38 Both sexes are equally affected. In one study, more than 50% of persons admitted with colonic ischemia initially were diagnosed with IBD. Because there is no specific treatment and outcomes usually are good, the difficulty in making the diagnosis does not cause significant morbidity.

Principles of Disease
